THE FRESH AIR TREATMENT OF ACUTE RESPIRATORY DISEASES, WITH ESPECIAL REFERENCE TO PNEUMONIA.*

By JAMES M. ANDERS, M.D., LL.D.,

PHILADELPHIA, PA.

PROFESSOR OF MEDICINE AND CLINICAL MEDICINE IN THE MEDICO-CHIRURGICAL COLLEGE.

It is a well-established fact that when a cure is brought about in any of the infections for which we have no specific remedy or serum, the day is with the resisting forces. It is equally true that a most marked fortifying influence of the human system is to be found in certain natural agencies, among which fresh air is one of the foremost. In line with the same argument it may be stated that the most successful treatment of the great white plague is hygienic rather than medicinal, although it is to be earnestly hoped that we shall one day be in possession of a specific serum.

Doubtless one of the principal reasons for the slow progress that has been made in the treatment of pulmonary tuberculosis up to within a comparatively recent period, and still is being made in the case of lobar pneumonia, notwithstanding the already voluminous and ever-increasing literature on the subject, is ascribable to the foundationless and misguided hopes, which are too often based on the products of the manufacturing pharmacist, instead of recognizing the curative value of natural elements everywhere available; I refer particularly to absolute rest, fresh air, sunshine, and appropriate feeding. We may, on reasonable grounds, count this professional propensity to ring in a long list of drugs in the treatment of this disease, the majority of which rest on nothing tangible, but are like Mohammed's coffin, suspended in mid-air, as most unfortunate.

It required a long period of time for the profession to learn the great value of an outdoor existence in the treatment of tuberculosis, but its superior value has been finally recognized by the medical profession; and it has been before the public long enough in almost every quarter of the globe to prove its efficacy beyond question. Let us hope that no passionate infatuation of the professional mind for new therapeutic remedies will in future proffer a substitute, or lead to the neglect of a practice so efficient as outdoor living.

To be effective, fresh, pure air must be constantly applied, without regard to the seasons of the year or the periods of the day, although a certain degree of protection can and should be afforded during climatic extremes and under different conditions of disease.

*Read before the American Climatological Association, Atlantic City, N. J., May 14, 1906.

Without doubt, the combined sanatorium and climatic treatment of tuberculosis has given the most favorable results in that disease. These sanatoria take the form, as a rule, of cottages, pavilions, and tents, the object being to provide the sufferers abundantly with pure external air both by day and night. I am decidedly of the opinion that, next to appropriate and vigorous feeding with fat-forming proteids, the most effective element in the treatment of tuberculosis is constant purity of the atmosphere which is breathed, and also that rest, in cases presenting fever, is no less important.

Whilst this view needs no defence at date of writing, and whilst also the progressive element of the medical profession is wholly convinced of the usefulness of fresh, open air in pulmonary tuberculosis, there is still much missionary enterprise needed among the rank and file of that profession. It should be well understood also that to be effective the open-air treatment, whether employed in tuberculosis or any other pulmonary complaint, must be carried out in connection with a rigid system of living under the personal supervision of a competent physician.

This is equally true of the fresh-air treatment of the ordinary acute respiratory diseases, particularly lobar pneumonia, which, for the sake of convenience merely, has been placed in this category. The vast benefits of admitting fresh air freely to the sick-room in cases of pneumonia have attracted the attention recently of a few clinical observers, and in view of the very leading importance of the subject it deserves more extended consideration than it has hitherto received.

Undoubtedly, the normal human system has to a remarkable degree the power of accommodation, and unless exposed for too long a period to atmospheric impurities, no diseased conditions are the result. On the other hand, it is well understood that chemical and bacteriological impurities of the air are one of the most important factors in bringing about increased susceptibility to the acute infections, including diseases of the respiratory tract. No attempt can be made here to assign to the various impurities their precise rôle of pernicious activity. Stevenson and Murphy[1] have well said: "The evidences of injury to health from impure air are found in a larger proportion of ill helath—*i.e.* of days lost from sickness in the year—than under other circumstances; an increase in the severity of many diseases, which, though not caused, are influenced by, impure air, and a higher rate of mortality, especially among children, whose delicate frames always give us the best test of the effect of food and air."

Long since (1862) Sir John Simon stated that with a single exception "the 300,000 (coal) miners of England and Wales break down as a class prematurely from bronchitis and pneumonia, caused by the atmosphere in which they live. The exception is important. The colliers of Durham and

Northumberland, where the mines are well ventilated, do not appear to suffer from an excess of pulmonary diseases, or do so in a slight degree only." Notwithstanding the fact that, as the result of the introduction of more effective ventilation systems in the collieries of England and America, coal miners have been down to the present day peculiarly liable to bronchitis, asthma, emphysema, bronchopneumonia, and fibroid induration (pneumokoniosis), which often leads to chronic ulcerative phthisis. It is true that in these cases the lung texture is lacerated and irritated, to be followed by inflammatory processes, by the inhalation of coal dust floating in the atmosphere.

The usual mode of infection with microorganisms, which have been allowed to accumulate in badly ventilated habitations, is exemplified in the case of lobar pneumonia, diphtheria, chronic phthisis, and other infections.

At all events, bad or vitiated air is an important contributing factor in the causation of this class of affections by furnishing a nidus for the propagation of disease-producing germs and by accentuating their virulency. The fact that most cases of bronchitis, bronchopneumonia, asthma, and other lung affections show an increased incidence during the variable and cooler temperatures of spring and autumn, as well as the maximum prevalence of lobar pneumonia during the cold season, or from December to April, as compared with the exemption enjoyed during the warm season, would suggest that a low temperature and other meteorological factors form important factors in their production.

Granting this view, it is undoubtedly true that thorough ventilation combined with appropriate clothing is our principal hygienic measure in obviating the diseases mentioned above. "While prolonged exposure during the cold, inclement season is fraught with danger, careful, judicious 'habituation of the body to cold air and cold water' becomes at once an efficient and successful prophylactic measure." As elsewhere stated, "may not the higher incidence of pneumonia in winter and spring be due not so much to the direct effect of the low temperature, augmented barometric pressure, and velocity of the winds, as to the closer confinement of the populace indoors, in the stagnant air of living-rooms from which the sunlight is excluded, and which tends to lower vitality and decrease resistance on the one hand, and to favor rapid multiplication and increased virulence of the specific poisons on the other."[2] Again there is an evident tendency, as shown by statistical evidence, for pneumonia and other respiratory affections to prevail most extensively in overcrowded districts and among the impoverished classes. While there is no convincing evidence "as to the exemption of persons living entirely in the open air and thoroughly well-ventilated dwellings, and not exposed to infection from others," no doubt can be entertained that the breathing of pure air greatly lessens the incidence of the disease.

Naturally, then, pure air is primarily an effective prophylactic agent against the immense majority of both acute and chronic respiratory affections. While the foregoing facts are scarcely if ever called into question by physicians, there is a deep-rooted popular prejudice against the too free admission of fresh air into the sick chamber in cases of pneumonia and other acute respiratory diseases for fear of contracting "cold."

In victims of severe acute bronchitis with lowered resisting powers, a chill constitutes a dangerous experience as a rule. Hence, such conditions permit an outdoor existence only in fine weather and in the milder climates or seasons. But frequent changes of the indoor air without incurring a strong draught favors the cure of cases of acute bronchitis even in elderly subjects and children. Moreover, this method exerts a hardening effect.

This method, if conscientiously and persistently pursued, exerts an especially favorable influence in chronic bronchitis during the racking oscillations of the average American climate.

Fresh air appropriately applied, then, is generally to be recommended in the usual forms of bronchitis. In cases of neurotic asthma, marked improvement is often witnessed as the result of a suitable change of air. Now, whilst we cannot meet the variable climatic indications of this disease at home, the immediately beneficial effect of a flood of fresh air from an open window during a paroxysm is so well known as to make the suggestion appear superfluous.

The popular notion that there is an antagonism between pure, fresh air and the commoner respiratory diseases is clearly unfounded, and the profession should concern itself with the important question of giving the public the needed enlightenment on the subject. It is to be recollected, however, that fresh, cold air such as ordinarily admitted into our sick-rooms in winter does not mean that the patient is bathed in or breathes a germ-proof medium. Indeed, a subtle diffusion of the microorganisms that produce pneumonia and lung affections may be in progress at the same moment. The virtue, therefore, of fresh, open air does not reside solely in the quality of pureness, but also and largely upon its low temperature and dryness.

Cold is admittedly an effective tonic, if not combined with an excessive humidity. It is well known, as previously intimated, that the human body readily endures marked variations and even extremes of temperature remarkably well without obvious danger. Prolonged exposure to extreme cold, however, may prove positively injurious and even fatal. The question here arises, Is the influence of cold equally well, or better, tolerated under conditions of disease, such as lobar pneumonia, than in health?

The consumptive, as all know, can sleep with wide-open windows during the winter and at minimum temperatures, touching -10° to -30° F., with vast benefits to his condition. I have observed the application of the same principle with certain modifications to cases of lobar pneumonia with remarkably happy results. The question arises, By what immutable laws of Nature is the favorable effect of a steady cold produced?

In the first place, it is an undisputed fact that when the temperature rises above the critical point (Ranke) the organism defends itself from injury by increasing heat dissipation; the heat is removed in part by radiation and conduction from the dilated surface-vessels. When the sweat-glands become active a large amount of heat is also carried off by evaporation, and obviously the drier the surrounding air the greater the loss of watery vapor in this manner.

The critical temperature, according to Ranke, is from 59° to 68° F., and it is the "optimum temperature for man, securing the well-being of the organism with least expenditure of energy on its

part." It is of therapeutic importance to recollect that a lower temperature demands more active tissue change and per contra, that a higher temperature demands special means for getting rid of the heat generated. Obviously, however, the resistance to cold drops below the limit just mentioned in pneumonia, first, because of the artificial devices in the shape of bed-clothes which afford protection, and, secondly, the increased production of heat due to the presence of the morbid process.

In combating high temperature in various acute infections it is recognized that we have an efficient measure in hydrotherapy (cold baths directly abstracting the heat of the body), and also that water at a low temperature (70° F. or lower) produces a decidedly favorable effect upon the nervous system by stimulating the nerve centers, which preside over the organic functions (*e.g.* respiration, circulation). It is by reviewing our knowledge of the influence of hydrotherapy in this class of affections that we can measurably appreciate the value of a dry, cold atmosphere, which must exercise an analogous effect.

Briefly analyzed, the bracing and tonic effect of a steady cold is as follows: The principal influence exerted is that upon the nervous system; this is evidenced by its calming effect and the refreshing sleep induced thereby. The appetite and digestion noticeably share in the beneficial influences of this natural agency. In this connection it should not be forgotten that in the cold climate the system demands more nutritive material than in a warm one, or otherwise there will occur a loss of bodily weight. Fortunately, it is found that patients treated with fresh air can take more nourishment than those subjected to other methods, and readily assimilate it. Under the influence of low temperature the heart's action becomes slower and the pulse-tension increased—a desirable object to be attained in the treatment of lobar pneumonia. Cold exerts a tonic influence upon the nerves and vessels in the skin, and indirectly it has an important effect in lessening the tendency to internal congestion. Again, cold acts potently in stimulating the respiratory function, and, as an immediate consequence, more oxygen is absorbed.

It is obvious that an atmosphere containing the full complement of oxygen is demanded in pneumonia—a disease in which a large proportion of the air cells are rendered functionless. In speaking of the treatment of bronchopneumonia in children, Northrup[3] pertinently remarks: "Nothing stimulates the heart better than a current of fresh, cool air upon the face. Fresh air stimulates the heart, reddens the blood, quiets restlessness, favors sleep, improves secretions and digestion; in short, meets most of the indications for treatment of pneumonia in infants."

It has been the custom within the last quarter of a century to select as winter health resorts stations at great altitudes and in northerly latitudes. This is particularly true of foreign countries, where the medical profession has learned the lesson that these mountain resorts are better tolerated by invalids than the ordinary lowland winters, although the latter is in closer proximity to the tropics. The explanation is readily found in the fact that in the Alpine valleys the winters are intensely cold, combined with dryness and stillness of the atmosphere; and such a climate is more easily endured and more wholesomely stimulating to the bodily functions than the less severe climate of the lowland with its "penetrating damp and windy cold."[4]

We no longer believe in the absolute necessity for high altitudes in the cure of pulmonary tuberculosis, but, on the contrary, the majority of present-day sanatoria are situated at lower levels. It is generally accepted as a fact, however, that sanatoria should be located by preference in northern latitudes rather than too near the tropics, because of the differences in the peculiarities and effects of the different climates, already set forth. From the same facts it may be inferentially stated that home winter climates possessing such features as penetrating damp and strong wind currents would necessitate the exercise of care and caution in applying the fresh-air treatment in cases of pneumonia, although with sufficient covering and the proper adjustment of screens the patients can be efficiently protected.

At first sight, it might appear that the fresh-air treatment would diminish heat dissipation by nature's own methods, since cold, fresh air tends to contract the surface vessels, and thus retard loss of heat by radiation and conduction as well as evaporation of the cutaneous exhalations. It is admittedly important to maintain an active state of the cutaneous circulation and the secretions and by means of bed-clothes the resistance to cold is greatly increased, and under these circumstances mild perspiration may even be induced by systematic tepid spongings, combined with simple diaphoretics. At all events, the theoretical objections which might be urged against the fresh-air treatment are more than balanced by the salutary influences mentioned above, more particularly the bracing effect of the dry cold, with purity of the atmosphere, both of which are the features of this mode of treatment.

Indeed, it is not my purpose to advocate the fresh-air treatment to the exclusion of other accepted methods and means in the management of cases of pneumonia, but as a valuable adjunct to what is already known on the subject. The question naturally arises, May not a patient catch "cold" if exposed to currents of fresh air from open windows? May not such conditions be conducive to the occurrence of the more usual complications of this complaint, more especially bronchitis? It is generally conceded that generalized bronchitis of severe grade is an ominous complication; it intensifies the febrile movement and augments the dyspnea and cyanosis as well as the tendency to cardiac failure.

A personal acquaintance with the fresh-air method, although somewhat limited, justifies the statement and belief that pneumonia patients are in no danger of contracting a cold from perflation of the sick room with fresh air, and that the mere breathing of fresh air or the flowing of cool air over the face while the patient is confined to bed is practically unattended with risk in this respect.

In a severe case of lobar pneumonia, which I saw with Dr. George M. Boyd during the past winter, the nurses in attendance were obliged to wear wraps; this was also true of other cases without ill effects. My personal experience of its use, however, is limited to only five cases—too few to base thereon reliable inferences—yet the uniformly favorable results obtained furnish strong encouragement to its more general adoption.

The fresh-air treatment should not be undertaken without due deliberation upon the peculiarities presented by the individual case. Thus, in

certain forms of secondary pneumonia it might be inadvisable, *e.g.* when pneumonia supervenes in the course of advanced Bright's disease, or in persons having a highly sensitive nervous organization, and the like. The response to the action of a steady cold, be it remembered, is not always the same.

In general terms, it may be said that this measure is contraindicated in exceptional instances only; hence there is no difficulty in selecting suitable cases for its employment.

Lastly, among the particularly beneficial effects observed from the constant breathing of fresh, cool or cold air are a better general condition and increased strength, an improved appetite and digestion, refreshing sleep, lessened severity of the cough, diminished breathing rate, fever and pulse rate; in short, a less marked toxemia than in cases treated by the more usual methods. The nervous system, however, partakes largely in the general favorable effects.

INDEPENDENT MEDICAL JOURNALISM A NECESSITY FOR THE PROFESSION.*

By KENNETH W. MILLICAN, B.A., Camb., M.R.C.S., L.R.C.P., Ed.

ST. LOUIS.

The *California State Journal of Medicine,* in its issue for January, 1906, quoted approvingly a statement from the *Journal of the Medical Society of New Jersey,* that "the day of the privately owned weekly medical journal is passing away. Its place will be taken by the *Journal of the American Medical Association* and the various State journals."

Let us for a moment suppose that this object has been accomplished and let us look at what the consequences of its accomplishment would be.

The American Medical Association is becoming a powerful, and therefore a formidable body. It can be powerful for good or for evil; in which direction its influence will be cast will depend entirely upon the character of the few men who from time to time must inevitably control its destiny. If they are earnest, honest, and tactful, its influence will make for good, as regards both scientific medicine and medical polity, including the liberty of the individual physician; but if they, or a majority of them—or even a minority of them, if that minority should consist of men of dominating force—lack any of these three essential qualities, the association will become a menace to the profession and through it to the public. For it must be remembered that while the system of government of the association *appears* to represent every member of the association, such representation fails practically, inasmuch as all the power is left, *without veto or revision by the general assembly,* in the hands of the House of Delegates, who, though nominally the overmen, are very liable indeed to be influenced by, and subservient to, the council. To say that the delegates are elected by their home constituencies, and must therefore adequately represent the profession, or at least that portion of it that constitutes the association, does not dispose of the objection to the inherent dangers of the plan; for the constituency is too far removed from the field of action—the *locus in quo,* wherever it may be, of the annual meeting—and the period of the session is too brief and its recess too prolonged, to safeguard the constituency against the very real and pressing danger of having schemes conceived and railroaded through any annual meeting, practically without reference to the wishes of the constituency at large. This danger is further increased by the filtering process through which the delegated authority has to pass before it reaches the council chamber of the national association. The county societies send their delegates to the State societies; the State societies in turn send their delegates to the national association; but it is the council which practically does all that is done; so that there is a constantly increasing leakage of current, so to speak, between the source of influence and the point of its application. That this idea is not imaginary is clearly demonstrated by the committal of the association to the purchase and future maintenance of a medical directory, before ever the matter had been broached to the constituencies. The fact demonstrates beyond a doubt how entirely and *arbitrarily* under the present system the association can be made the controlled instead of the controller. I am using this merely by way of illustration. I am not prepared to express any opinion on the desirability or otherwise of the directory matter—indeed, not being a member of the association, I do not claim any right to do so; but as a member of the profession at large, I do claim the right to observe whither the possibilities of the present organization scheme *may* lead—and land—the association, and through the association's influence every member of the medical profession. For there is abroad in this country, as well as in England, a spirit which is thus frankly expressed by a writer in the *British Medical Journal* for May 19, 1906: "it becomes us as an Association to discourage dissent among ourselves when, as we know, the day is not far off that the British Medical Association *will govern everything connected with the British medical profession.*"* In like manner we fear that the object of this over-elaborate organization of the American Medical Association is not merely to aid "the great aim of Nature, intellectual improvement" and to assist in the procuring of improved conditions of public health and safety, but to *govern everything connected with the American medical profession.* Now, in our opinion there is altogether too much "governing" being done in the present day. It is not "governing" of which the profession—and indeed the world—stands in urgent need to-day, but cooperation towards intellectual development. Let us ponder over the words of one of the greatest medical philosophers that has ever ornamented our profession, the late Dr. John William Draper, who says in his *History of the Intellectual Development of Europe*:† "It is to the honor of both these professions [lawyers and physicians] that they never sought for a perpetuation of power by schemes of vast organization, never attempted to delude mankind by stupendous impostures, never compelled them to desist from the expression of their thoughts, and even from thinking, by alliances with the civil power." If he were alive to-day, would he not view, think you, with jealous, anxious, and watchful eye, this threatened honor of the medical profession? In truth, "Eternal vigilance is the price of" liberty, as well as victory.

The association has grown too unwieldy to be managed in any other way than through some form

of delegated authority. Now, all history shows us, and all business men have found out for themselves and invariably act upon the principle, that no great body can ever be made workable, except through the dominating influence of a master mind or minds. There is not, never has been, and I believe never can be, such a thing as an ideally representative government, in which every unit shall have his just and proportional share of the responsibility, for the simple reason that "large bodies move slowly," which is tantamount to saying that in the "continuous adjustment of the organism to its environment" they are unworkable. By a process of continued delegation of authority the actual power must ever ultimately resolve itself into either a dictatorship or an oligarchy, in effect, if not in name. The nearest approach to a really representative government was that organized by Solon for the Athenians, in 594 B. C., as modified by Kleisthenes, in 510 B. C., in which the principle of a working council to consider conditions, prepare remedial measures, and expound them to the general assembly of the whole, who then accepted or vetoed them by their individual votes, secured both practicability and the safeguard of a direct popular control. But it is just this safeguard that the present constitution of the American Medical Association lacks and therein lies the danger. Power is the essential of government; it is necessary to all action. Power implies concentration; diffusion implies weakness. But man is so constituted that, with very rare exceptions, the possession of power suggests with the force of an obsession its exercise in the direction of the individual benefit of him who wields it. When, therefore, power which belongs to the whole is intrusted for execution to a part, it is a paramount necessity that some check should be retained in the hands of the source, lest the part become greater than the whole; a condition which—however impossible to mathematics—history, viewed as fact, has demonstrated to be practically possible, and viewed in the light of philosophy, to be inevitable.

It is therefore clear that if not now, at some future time—a matter dependent solely on the *personnel* of those into whose hands the delegated executive authority shall fall—under the present constitution of the American Medical Association, a tyranny—whether individual or oligarchical does not matter—will arise, in which the few will rule and the majority will be ruled. Issues will crop up in which the few, who, from the necessities of the case must assume responsibility, will dictate one course, while the majority will prefer another but will be powerless to enforce their preference, for a long time, at any rate. Of course, ultimately the matter will readjust itself, as always happens, by a revision of the conditions; but meantime what will take place? The few will have all the machinery of organization in their hands; the majority will be so many isolated units, powerless, because of their isolation. The pages of the official organ will be controlled by those who control the organization itself, and since the admitted purpose is *that it shall be the only medium of communication between members of the profession* (according to the dictum upon which this paper is based), there will be no opportunity for the malcontents, however numerous, to get together and organize in opposition to the oligarchy. As I have said, these things will always right themselves in the long run. When the tension becomes too great to be borne, the man and the occasion will ultimately arise, the thunderstorm will burst, and the atmosphere will be cleared. But in the meantime, what? Years perhaps, of oppression, of injustice, of futile kicking against the pricks, because the many individuals have no channel through which they can come together, can make known their views to one another, and can learn the extent to which their opinions prevail. Each man, with a few of his acquaintances, will realize his antagonism to the powers that be; but while the latter will present their views with a solid front, the former will remain in ignorance of the fact that scattered throughout the country are thousands of their fellows chafing equally with themselves, and that if they could only join hands the usurping oligarchy must fall before their united attack.

If it is true in commercial life that competition is essential to the public welfare, and that monopoly leads to tyranny—and can any one deny that that lesson is being borne in on the world with daily increasing force?—it must be equally true that to permit the establishment of a monopoly in medical journalism will be to sound the knell of medical liberty. The American Medical Association is, in essence, an excellent institution. It exists. It must continue to exist. Its journal can be a powerful instrument for professional and public welfare. No large association is workable, except on the principle of the intrusting of the power in the hands of a few. But the exercise of that power *must be fully safeguarded;* first, by a right of affirmation or veto on the part of the general assembly; and secondly, by the maintenance of independent means of communication that shall afford a means of expression to the dissenting factor, so that it may gauge its strength and learn whether it does not represent more truly than the delegated authority the opinion of the whole.

But there is another side to this question. Many a nefarious scheme has been borne to victory by the use of an incontestably worthy object as a slogan. The *Journal of the American Medical Association* has indubitable right on its side—whether its motives be pure and singleminded or not, is a question I am not called upon to decide—in a demand for a measure of publicity as regards the composition, and of honesty in regard to the claims, of proprietary remedies, those exploited to the physician as well as those offered directly to the public. Speaking to this association at its annual banquet at Atlantic City, in 1904, which I attended as the guest of its president, Dr. Sajous, I then insisted, when the question of advertising and of reading notices was under consideration, that what was most needed and what should be insisted on in the advertising world was *honesty*—the not proclaiming the thing that is not, or denying the thing that is, but everything showing for what it is. I recall distinctly a certain sense of having had cold water thrown over my ideas by one who is now in the forefront of the extreme clamorers for purity and honesty. Some of you may remember it.

But we cannot conscientiously join in the outcry that has been properly raised—and it is immaterial whether that outcry is due to a singleminded devotion to the public good or is simply the crafty use of a worthy object for purely selfish purposes—against patent medicines and nostrums that prey upon the public to its detriment, so long as we do not hold fast to first principles in regard to those preparations that appeal to us for our sanction. As the result of a careful and honest attempt to analyze the legitimate requirements of all parties in this controversy we published in the *St. Louis Medical Review* of *December* 30, 1905, a series of propositions which, with your permission, I will recapitulate, and which I think supply a basis upon which can be erected a rational touchstone, equally fair to the legitimate interets of the public, the profession, and the commercial man. They are as follows:

"(1) The spirit of 'commercialism' lies in the fact that the primary object sought is the material benefit of the individual; public benefit is, when present, a

secondary and incidental motive. (2) When these ends are sought honestly, not pretending the thing that is not, or denying the thing that is, and when they are sought in a legitimate sphere, that is honest commercialism. (3) In professionalism, the primary end is the rendering the service of a vocation; the reward is secondary, and is based on the theory that 'the laborer is worthy of his hire.' It is not accumulation of gain, but livelihood, that is looked for. (4) The physician must either prepare his remedies for himself or engage commercial men to prepare them for him. (5) Pharmacy is a commercial pursuit. (6) It must therefore be judged on commercial principles and its reward must be calculated in terms of gain, not of mere livelihood. (7) This implies the equity of acquiring property right in the results of labor, knowledge, exploitation, convection, and all the various factors that enter into a successful commercial undertaking; and so long as the methods are honest there is no sound reason why physicians should oppose it. (8) Proprietary medicines are in many instances only vastly more elegant, palatable, and in every way superior, forms of the various stock mixtures kept at hand by every dispensing physician, and to be found in every hospital formulary and even in the various national pharmacopœias, for use either alone or as a base, as occasion may require. Therefore (9) a proprietary is not objectionable simply because it is a proprietary. (10) Nor because it consists of a mixture of substances in place of being a definite chemical compound. (11) It is objectionable if, being a definite chemical compound, its chemical constitution, or being a mere mechanical mixture, its essential component ingredients are kept secret. (12) It is objectionable if, while containing any potent drugs, of marked physiological action or toxic character, it is exploited to the laity. (13) This objection,* however, cannot reasonably be made to apply to remedies of known composition, therapeutically classifiable as laxatives, tonics, and the like, which contain no potent or toxic drugs, but may be regarded as legitimate domestic medicines; to mineral waters and beverages as such, to external applications, disinfectants, nutrients, and the like."

Acting upon these principles the *Review* has established the following as its standard whereby an advertisement is judged as to its eligibility or ineligibility:

"We therefore shall not accept in future, and we have advised all our present advertisers that we shall not renew for 1906, the advertisement of any remedy that does not give its *essential* constituents, so far that the physician using it may know, or can ascertain by reference to a Dispensatory or a standard textbook of therapeutics, its physiological action and therapeutic character; and if it contains drugs of pronounced potent physiological effects or toxic character, the amount thereof that he is giving."

I think, gentlemen, that in the foregoing propositions we have honestly and with no ulterior motive, stated the case fairly and equitably for all parties concerned in the present controversy, and it is to me a source of particular gratification that the *Review* has lost only two advertisements as a consequence of insisting on compliance with these principles.

Let us at least, lay down for ourselves—if necessary, each one for himself—a certain definite set of principles which shall govern the admission or rejection of advertisements in the columns of our papers, publish them, and act upon them; by so doing we shall gain the sympathy of many within the association who are aware of the peril that the abolition of independent journalism would entail, but who are firmly and properly convinced of the necessity for some reform in the matter of proprietary medicine advertisements. Experience has convinced me that a moderate course will satisfy the wisest among these, and that a moderate course also, receives the approval of the vast majority of reputable advertisers.

One thing more. It has been said, "Oh, that is all very well, but what guarantee have you that these manufacturers who have 'complied' with your requirements are not fooling you?" I can only shrug my shoulders at such a question. If I write a prescription to-day for purely pharmacopœial products what guarantee have I that the druggist compounds it properly, especially if it suits his interest or convenience to make a change? We *must* trust somebody all the time, in every phase and relation of our life, and I absolutely decline to believe that there is a greater percentage of dishonesty in any one class of any community, or nationality, or religion, or political party, or anything else, than in the other classes. Scoundrels there are, no doubt, among drug manufacturers, as among all other kinds of commercial men, among retail druggists, clergymen, lawyers, physicians, politicians; but, to bring the matter to an *argumentum ad hominem,* because the newspapers daily record instances of marital infidelity is it necessary that every man should look upon his wife with suspicion? This attitude of perpetual suspiciousness indicates a contemptible nature. There is a certain proportion of bad in the world and any one of us may be the unlucky victim of it in one direction or another; but it is neither wise nor right to let it poison our minds in all relations of life. We trust people until we have particular reason to believe those people dishonest. When we find them so, the sensible man just strikes them off the list and looks for some one more worthy of his confidence. But he does not accept as gospel truth every *ex parte* statement that is made by every professional agitator.

To sum up the argument, then, I will, if permitted, quote the following editorial remarks from the *St. Louis Medical Review* for April 7, 1906: "The primal passions and emotions are to-day exactly what they were 2,000 years ago, and there is no reason to doubt that 2,000 years hence they will be exactly what they are to-day. Their mode of expression has altered, that is all. 'Robber barons,' it is true, no longer go forth a-foraging with the strong arm to ravage and waste and plunder; but have we not trusts, corners, combines, which effect with the astute brain exactly the same ends, from the same motive—lust of power, inherent, primal, eternal, as the pride of possession, the promptings of sex, the instinct of life itself? We aim these remarks at no one in particular; it is man, not men, that is to blame. When organization shall have stamped out all individualism, have suppressed all independent journalism, it will have rendered impossible for the minority all expression of dissent; then will it, perchance, be found that the guns mounted for the defense of the city have been seized and turned upon the city itself while men slept."

In conclusion, there is no more dangerous state of mind than that of the fanatic who thinks his mission is to reform the universe. Scholars have spent much time in discussing whether Hamlet was mad. Personally, I have no doubt that he was, and I base my belief on one couplet alone, which I consider ample demonstration of the fact:

> "The time is out of joint;—O, cursed spite!
> That ever *I* was born to set it right."

*To exploitation to the laity.

INFECTIONS BY THE BACTERIUM COLI COMMUNE WITH PARTICULAR REFERENCE TO THE URINARY TRACT.*

By CLARENCE A. McWILLIAMS, A.M., M.D.,

NEW YORK.

INSTRUCTOR IN SURGERY, COLUMBIA UNIVERSITY, NEW YORK; SURGEON TO TRINITY HOSPITAL; ASSISTANT SURGEON TO THE PRESBYTERIAN HOSPITAL.

THE text for my paper this evening was furnished by a patient who has recently been under my care. Before relating the details of this case, however, I shall take a few moments in stating some of the facts which have been found out as to this remarkable microorganism.

The colon bacillus is a short, thick, straight rod with rounded ends. Its length is on the average three or four times its breadth. It forms no spores and has a moderately active motion, and is found by twos, in small chains, or in groups. It ferments glucose and lactose, produces gas and indol, curdles milk, and gives a neutral red reaction. It represents great variability as to biological and morphological characteristics, such as movement, cultural peculiarities, virulence, etc., on which account there are recognized "colistämme," which, taken as a whole, form the group of the colon bacteria. This marked polymorphism has caused in the past much confusion and discussion with reference to its relations and properties. The virulence and reproductivity of colon bacilli are considerably decreased under the influence of an oxygen free atmosphere. It is an aërobic, faculative anaërobic, non-liquefying bacillus. This fact may possibly be of importance in the relations of the microorganism in the intestines. It produces marked toxins which Vaughan has shown are intracellular. It gives a specific serum reaction which is not as yet diagnostically useful, but is, however, an interesting fact.

Whether the colon bacteria possessed pathogenic properties was for a long time an unsettled and disputed question. It seems now, however, well established that it is a true pyogenic organism, setting up various inflammatory conditions in widely varying portions of the body. Animal experiments amply prove this point. Emmerich found that injections in guinea pigs produced severe gastro-enteric catarrh with cholera-like diarrhea, constitutional symptoms of fever, which were followed later by subnormal temperature, nervous and cardiac symptoms of various kinds, peritonitis, abscesses in liver, spleen, etc., and the appearance of general sepsis. The toxins are the substances which seem to cause death. Injections of cultures into the pleural and peritoneal cavities, into the urinary and gall-bladders produce purulent or serofibrinous inflammations. Several facts seem clear:

1. The colon bacterium varies both in its virulence and pathogenesis.

2. The resistance of the individual to colon bacterial infections is profoundly influenced by the state of the body nutrition.

3. There is little virulence of colon bacilli in cultures from healthy intestines.

4. There is much greater virulence in fresh cultures when taken from diseased intestines than from healthy.

In the healthy man we know that the intestines, particularly the lower, swarm with these bacteria. It has been estimated that 126 billions of bacteria are passed by an adult in 24 hours, and that at least a third of the dried substance of the feces consists of bacteria. With a normal intestine these microorganisms, when taken by mouth or when injected directly into the intestine, are harmless, whereas, when injected into the circulation, serious lesions and even death result. It is pertinent to inquire, then, why do not the colon bacteria in the normal intestine produce disease? We may account for this in several ways: (1) Either the poison must be decomposed in the intestine, or (2) it is held back by the liver and made harmless, or (3) it is not absorbed.

It seems certain that the intact epithelium of the intestines does not absorb the bacteria or their toxins. This absorption occurs only when there is a break in the mucous membrane. For example: as a result of the circulatory disturbances, and its attendant epithelial loss and necrosis, which occur in the walls of the intestine in a strangulated hernia, colon bacteria soon swarm in the fluid in the hernial sac. Experimentally this occurs in ten hours. Likewise severe, long-continued constipation seems to allow the bacteria to pass through the intestinal walls. In this way we find that metastatic abscesses may be formed. Examples of this on record are: A wound, following a thyroidectomy, subsequently suppurated and from the pus pure cultures of colon bacteria were obtained. The same occurred in a pneumonic consolidation following a strangulated hernia operation. Cases of liver abscesses resulting from diarrheas and giving pure cultures of colon bacilli are numerous. Colon bacterial septicemia is frequent in the new-born; this has a malignant course with hemorrhagic manifestations. An epidemic among the new-born was observed in Poland, in which there were icterus, cyanosis, and bloody diarrheas, but no fever; death resulted in from one to four days; postmortem, all the organs were found to contain colon bacteria; the cause was traced to a spring infected with colon bacilli. This microorganism likewise seems to be an undoubted producer of peritonitis and gall-bladder diseases. The bile is normally sterile and has no bactericidal qualities, but on the contrary is a good culture medium (Escherich and Pfäundler). Stagnation of the bile is necessary for bacteria to produce deleterious effects. Injections of colon bacteria in a normal gall-bladder produce no abnormal or pathological results, but twenty-four hours after aseptic ligation of the common duct in rabbits colon bacteria can be cultivated from the bile. It is believed that the "stone-forming biliary catarrh" is the result of the invasion of colon bacteria. This microorganism, in addition, has been isolated in pure cultures from abscesses, osteomyelitis, peritonitis, pleurisy, pericarditis, inflammations of the genitourinary organs in both sexes, meningitis, arthritis, inflammations of the biliary passages, hepatic inflammations both acute and chronic, otitis media, conjunctivitis, pancreatitis, appendicitis, and mastitis, and it may be the only demonstrable lesion in infected wounds, inflamed hernial sacs, splenic abscesses and infarcts, etc. It has been obtained in pure cultures from the blood, and is a cause of septicemia and pyemia. Howard reported a case of colon meningitis which followed an anal operation. In three children who died from colon meningitis, colon bacteria were found in pure cultures from the pus from the ears.

With this necessarily brief, introductory résumé of the more general characteristics of this remarkable microorganism, I desire to consider more specifically the lesions which it produces in the urinary tract.

Bacteriuria has been recognized as existing for a long time. Perhaps the most typical and best known

*Read at a meeting of the Hospital Graduates Club, February 22, 1906.

is that found in typhoid fever, where the typhoid bacilli are excreted from the blood by the kidneys. It usually produces no lesions or symptoms. Bacteriuria due to the colon bacilli we may divide into two classes as to origin;

1. Ectogenous, or bacteriuria from external causes. This is always prostatic or vesical in origin and is due to bladder injections, the use of the catheter or sounds, etc. It is usually benign and has a good prognosis, therapy being necessarily directed only towards the local lesion. Occasionally we find the infection ascending into the pelves and kidneys, either unilaterally or bilaterally.

2. Endogenous, or bacteriuria from internal causes. This variety will alone occupy our attention. It differs totally from the preceding in that (*a*) the bacteria arise in some other part of the organism and pass into the urine; (*b*) their origin is oftentimes difficult to trace; (*c*) it is very rebellious to treatment because the primary focus must first be treated and cured before the bacteria can be eliminated from the urine.

It will at once be asked how the urinary tract becomes infected in endogenous bacteriuria? In answer to this we may say that there are two routes, as follows:

1. By the migration of the bacteria from an organ infected with this organism to a neighboring portion of the urinary tract—that is, by direct contact.

2. By the excretion by the kidneys of bacteria circulating in the blood, absorbed from some primary focus.

Rostoki makes the statement that 80 per cent. of all infections of the urinary tract are due to colon bacteria. This is especially true in children and in women. Cnopf reports forty children who had colon bacterial cystitis, thirty-two being girls and eight boys. All had suffered from enteritis, which he considered the source of the infection. Wreden found that by injecting colon bacilli into the rectum after traumatizing it, colon bacteria could be recovered from the urine in the bladder. He also demonstrated by the microscope that oil and vaseline can be transmitted directly from the rectum into the bladder. A number of observers have isolated colon bacteria from the blood of children sick with intestinal diseases. Trumpp has examined the bladder contents of seventeen children who were ill with follicular enteritis. None of these had had any bladder symptoms, yet in fourteen, nine girls and five boys, he found colon bacilli in the urine. In men we may say that the most frequent endogenous, or internal, method of infection is by the intimate contact of the rectum with the prostate, favoring the emigration of bacteria from the rectum directly into the bladder and prostate. This probably occurs through the medium of the lymphatics. In women the shortness of the urethra as well as the nearness of the meatus urinarius to the anus favors the entrance of the bacteria by way of the urethra. Infections through the medium of the general blood-current seem to occur equally in the two sexes.

Infection of the prostate may remain limited to that organ, producing continuous or intermittent bacteriuria, or it may extend to the bladder. This cystitis may remain localized in the bladder or the inflammation may extend upwards into the pelves of one or both kidneys. This ascending infection occurs in one of several ways: 1. Upward through the ureter. Bond (Address in Surgery before the British Medical Association, 1905) recorded that he applied sterilized indigo granules to the orifices of various mucous passages and found that the granules were somehow transmitted up these passages in the face of the natural stream of contents, and after a day or two could be identified at various distances above. Thus, indigo applied to the lips of the uterus was found a day or so later in a pyosalpinx, an in another case even in the peritoneum around the ostium abdominale. Indigo placed in the rectum was found in a cecotomy wound three days later, although the bowels had been opened in the interim.

2. Along the lymphatics the infection may be transmitted upwards. The lymphatics of the prostate, seminal vesicles, and bladder connect directly with the lymphatics along the course of the ureter, which in turn connect with the lymphatics of the hilum of the kidney, and these with a subcapsular network around the kidney, which likewise sends branches into the cortex of the kidney and into the fatty capsule surrounding it.

We then have frequently, in an ascending infection, the following sequence of events: prostatitis, cystitis, ureteritis, pyelitis, suppurative nephritis with or without miliary abscesses, diffuse interstitial or parenchymatous nephritis. From the kidneys the organisms may press into the general circulation and produce septicemia or pyemia. Schmidt reports a case of ascending pyelitis in which colon bacteria were found in the pus taken from the knee-joint.

The kidneys are usually the first organ of the urinary tract infected when the general circulation contains bacteria absorbed from some primary focus, such as the intestines, etc. From the kidneys as starting points, there may be descending infections of the pelves, bladder, etc. Lastly, the kidneys may be primarily infected by the direct extension to it of an inflammation in the colen, such as rectocolonic appendix abscess, etc.

Barnard (*Lancet,* October 28, 1905) reports a number of cases of multiple, unilateral abscesses of the kidney, due to acute ascending infections of the normal urinary tract by the colon bacilli. The majority of these cases were treated by nephrectomy and the remainder by nephrotomy, with great success. Janet reports a number of cases of bacteriuria resulting from mucomembranous enterocolitis. Not until the colitis was cured was there any benefit seen from treatment of the bacteriuria.

Every attack of constipation doubtless sends myriads of colon bacilli through the kidneys, and from every infected wound a sufficient number of streptococci and staphylococci enter the circulation and pass through the kidneys, to cause suppuration many times over in those organs, if only they are vulnerable, but this is not the case. Unless there is some trauma, irritant, or congestion, the bacteria are passed off without so much as multiplying in the urine (Keyes). It is believed nowadays that the spontaneous infection of patients with enlarged prostates is due to the absorption of colon bacilli from the intestines as a result of constipation, hence great stress should be laid on keeping the bowels of prostatics clear in order to avoid this possible source of danger. While not generally appreciated, it is undoubtedly true that urinary disturbances seen in cases of appendicitis are often due to the presence of colon bacilli in the urine (Lancien, Thesis Paris. 1902).

Sir J. Barr (*British Medical Journal,* January 20, 1906), in an article on arteriosclerosis, says that he has suspected for some time that the toxin of the colon bacillus was an important factor in the production of this disease, for examination of the blood of arteriosclerotics showed that in 55 per cent. of the cases it gave complete agglutination with the

colon bacillus, as compared with only 20 per cent. with the blood from persons free from arteriosclerosis. Flexner has called attention to the fact that chronic Bright's disease and uremia are often complicated by a terminal infection with the colon bacillus. Hence the necessity for careful attention to the intestinal condition in patients with nephritis.

The frequency with which colon bacilli are found in infections in the various parts of the urinary tract is shown in the following tables:

Cystitis: Krogius found colon bacteria in 16 out of 20 cases; Morelle, in 13 out of 17; Denys, in 17 out of 25; Melchior, in 24 out of 35; Douglas, in 14 out of 20; Brown, in 31 out of 60; Schmidt, in 60 out of 73; Rostoki, in 80 out of 120. Total, 255 out of 370 cases, or 69 per cent.

Pyelonephritis: Albarran found colon bacteria in 15 out of 33 cases of ascending pyelonephritis; Schmidt, in 12 out of 14; Savor, in 13 out of 19. Total, 40 out of 56 cases, or 71 per cent.

Infections of the whole urinary tract: Escherich found colon bacteria in 58 cases out of 60; Brown, in 38 out of 80. Total, 96 out of 140 cases, or 68 per cent.

The effect of the colon bacterium on the urine is not to disturb the distribution of the nitrogen in urea, ammonia, and non-urea compounds. The urine containing this bacillus is not decomposed, but retains indefinitely its normal reaction to litmus. While remaining acid, the urine acquires a characteristic pungent odor, readily recognized, sometimes almost fecal, and shows a thick, viscous deposit. This persistent acidity of the urine is characteristic also of cystitis caused by the tubercle and typhoid bacilli and by the gonococcus. The ordinary pyogenic organisms always cause an alkaline cystitis. In a pyelitis unattended by cystitis the urine is almost invariably acid.

Diagnosis.—It must be borne in mind that suppurative nephritis and pyelitis are not independent conditions, although undoubtedly the inflammation has its beginning in the one or the other. It is impossible to distinguish clinically pyelitis without nephritis, or nephritis without pyelitis, except only those rare cases of renal abscess which begin in the renal parenchyma and do not implicate the pelvis. With this one exception, suppurative nephritis does not occur without pyelitis, nor does pyelitis, whether catarrhal or suppurative, occur without nephritis (Keyes).

To treat thoroughly and intelligently patients with urinary infections, it is essential to ascertain certain facts:

1. The past and present history, with particular reference to infectious diseases, bowel disturbances, venereal diseases, etc., onset and symptoms of the present difficulty.

2. Etiology of the infection—whether from external or internal causes, and, if internal, where the primary focus is located.

3. The nature of the infecting organism ascertained from cultures of the urine drawn by sterile catheter, etc.

4. Careful physical examination, including that by means of the cystoscope and the ureter catheter in appropriate cases, and this is to be supplemented by repeated complete chemical and microscopical examinations of the urine.

5. What organ or organs in the urinary tract are involved?

6. Is the infection an ascending, descending, or stationary one?

Simple bacteriuria is the presence of great numbers of bacteria (most frequently the colon bacilli) in the urine without obvious parietal lesion. Subjective symptoms are absent or there is only slight frequency of micturition.

The urine shows an even dusty cloudiness which is present equally at the beginning as at the end of urination. It is acid in reaction and has a peculiar sickening odor. There is no deposit on standing nor is the haze affected by heat or chemicals unless albumin is present. In a drop of the urine under the microscope can be seen innumerable, squirming colon bacilli intermingled with a few epithelia and leucocytes. This condition may continue for weeks or months, to disappear spontaneously, or to go over into pyelonephritis, cystitis, prostatitis, etc. The lesser grades of colon cystitis differ from simple bacteriuria only through greater tenesmus and burning on micturition, the increase of mucus and pus cells in the urine, tenderness over the bladder, etc. It is a common mistake to call every case of pus in the urine "cystitis." This is most erroneous, for the three characteristic symptoms of pain, pus, and frequency of micturition are often due to such widely differing conditions as pyelonephritis, prostatitis, and seminal vesiculitis without the vestiges of any cystitis whatsoever. Again the inflammation of the bladder is often only one part of an inflammation of the whole urinary tract. Therefore the surgeon has two problems to solve (Keyes): (1) The existence or absence of cystitis; (2) the presence or absence of pyelonephritis, prostatitis, and seminal vesiculitis.

A few points only can be mentioned in the differential diagnosis. In cystitis the urine is always purulent throughout both the first and second glasses. Pus from the kidney sinks to the bottom of the glass and forms a compact level base, like sand, while bladder pus, on the contrary, forms a billowy, fluffy deposit, and often does not sink fully to the bottom of the glass, but remains more or less suspended in the fluid. When cystitis and pyelitis exist together, a very simple test often suffices to distinguish them (Keyes). After the patient has urinated in two glasses the bladder is gently irrigated with a hot boric-acid solution until the fluid returns clear. An hour later the urine is drawn with a catheter, and if it is then as purulent as the second glass before the bladder washing, the pus comes from the kidney. In patients with pyelonephritis we always find in the urine pus, bacteria, albumin, renal casts, and epithelia with possibly deficient excretion of solids, and on physical examination we may elicit tender and enlarged kidneys. The relation between the albuminuria and the pyuria is one of the most valuable means we have of differentiating pyelitis from cystitis, the best being probably ureteral catheterization.

Chronic cases of colon-bacillus infections of the urinary tract often simulate closely tuberculous inflammations. Very recently Allen (*American Journal of the Medical Sciences,* March, 1905) reported a case of chronic pyelitis, diagnosed as renal tuberculosis by himself, and operated upon as such, which proved to be an infection of one of the kidneys with a pure culture of the colon bacillus.

The presence of complicating calculi in the renal pelvis, ureter, or bladder must always be considered as a possibility.

The bacteriology of the intestinal microorganisms is fully discussed in the *Münchener medizinische Wochenschrift,* Nos. 37, 45, and 46, 1905. These researches set at rest many speculations as to their functions of the bacteria in the intestines. It seems certain that the colon bacilli elaborate materials which exert marked inhibitory influences upon the putre-

factive bacteria in the intestines, particularly the *Bacillus putrificus coli*, and in this way prevent the origin of intestinal autointoxication. The same is true as to its inhibitory effects upon the growth of typhoid, paratyphoid bacilli, etc.

The history of my case is as follows: The patient was an intelligent, well educated man of fifty, single, and free from any previous venereal taint. Five years prior he had been operated upon for a gangrenous appendicitis of severe course. Following this for a full year he had a severe type of ulcerative colitis, from which he recovered, but which left him with an irritable condition of the colon and rectum. From time to time there occurred attacks of diarrhea with mucus in the stools. The patient was exceedingly gouty, the disease manifesting itself in neuralgias and muscular pains, for which he spasmodically dieted. As is so often the case in gouty patients, who seem predisposed to bowel disturbances, he was able to control fairly well the looseness of the bowels by the use of the salicylates. The urine had always been free from albumin and casts, but after the ingestion of a moderate amount of sweets, sugar would appear in the urine, only to disappear on cutting off the sweets. For a year prior, the man had been tormented with pains in the rectum and anus, from which there was a protrusion from time to time. Examination on December 18, 1904, revealed an exquisitely tender ulcer, the size of a silver dollar, situated on the anterior aspect of the sphincter ani and extending up the rectum for about two inches. In addition there was a number of fair-sized hemorrhoids. On December 23, 1904, one of our most distinguished and competent rectal specialists, under chloride of ethyl and ether anesthesia, dilated the sphincter, removed the hemorrhoids by the clamp and cautery method, and thoroughly cauterized the ulceration, after partially dividing the sphincter ani with the knife at the place where the ulcer impinged upon it. Catheterization was necessary that night at 5 P. M. and the next morning at 11 A. M. Preliminary to the passage of the catheter the hands were washed as well as the glans, and a new, previously unused catheter was boiled for ten minutes. If ever infection of the bladder by a catheter could be excluded, this would seem to be one of the times. Thereafter the urine was normally voided. Conditions remained without incident until the evening of the third day after the operation, when the temperature rose to 101.4°, the pulse was 100, and the patient began to urinate every hour. On the fourth day the bowels moved for the first time as the result of an enema. Vesical tenesmus then began to be torturing and was incessant. The temperature rose to 102.8°. On December 29, the sixth day after the operation, the conditions were much worse, the patient became delirious and unmanageable, the pain with each urination was excruciating and intolerable, micturition occurring every few minutes. The temperature was 102° at noon and 104.4° at midnight. Examination of the urine for the first time after the operation, on December 30, the seventh day after the operation, by Dr. H. T. Brooks, showed the following: sp. gr. 1020, excessive white sediment, acid, 10 per cent. of albumin with Heller's test and a strong trace with Esbach's, no sugar with Fehling's and Nylander's tests, urea 2.3 per cent., phosphates and chlorides normal, indican excessive, occasional hyaline casts, coarse granular, epithelial, and mixed casts, innumerable isolated and masses of pus cells. Forty ounces were passed in the twenty-four hours. Dr. Brooks made the note that the albumin was undoubtedly of renal origin. It was self-evident then that we had to deal with an infection of the whole urinary tract. If the bladder were the first organ involved, the inflammation had very rapidly ascended to the pelves and kidneys. Possibly the infection absorbed from the raw areas in the rectum was carried to the kidneys first by the blood and in descending had infected the bladder. These points will be discussed later. On December 31, the eighth day, the temperature in the morning was 99° and at 10 P.M. 102°, and pulse 88. No chills or sweating. Muttering delirium with intervals of consciousness. Excessive vesical tenesmus. Without catharsis, very loose movements with blood and much mucus, and considerable rectal tenesmus occurred. On January 3, the eleventh day, a culture of the urine drawn by sterile catheter showed (Dr. Brooks) "the biological and morphological characteristics of *Bacillus coli communis*, and it is my belief that this is the main if not the only factor." One hundred and twenty-eight ounces of urine were passed in the twenty-four hours (due to large amount of ingested water), sp. gr. 1007, acid, 5 per cent. albumin, normal indican, chlorides and phosphates, numerous casts, and much pus; no blood. The patient was wildly delirious at times. Urination was involuntary and frequent. Highest temperature, 101°. Conditions remained the same until the fifteenth day, January 7, when all the symptoms became worse: Wild and noisy delirium, frequent, painful, and involuntary micturition; the eyes were much swollen with edema and a conjunctivitis was present, probably due to infection carried to the eyes by the fingers. The urine contained 30 per cent. of albumin, indican excessive, and innumerable casts. This examination showed that the cystitis had lessened, but the nephritis had increased. The question which then caused the greatest anxiety was to what extent the infection would go on to involve the kidneys. The eye condition now gave grave concern for a number of days. The edema became worse and involved all the structures external to the sclera, and the lids were nearly closed. There was no edema elsewhere in the body. On January 12, the twentieth day, there began some improvement in the renal and vesical conditions, the albumin being 15 per cent. On January 14, the twenty-second day of the disease, the eyes markedly improved, coincident with an improvement in the urine, of which forty-one ounces were passed in twelve hours, showing slight trace only of albumin, excessive indican, urea 1.4 per cent., casts and pus the same. There was also some improvement in the delirium, which was not so wild, although the patient was constantly irrational and very restless, and needed to be continually watched, as he had a fixed idea that he was being poisoned by his attendants and that he must get out of bed to avoid them. General improvement continued until January 18, the twenty-fourth day. At this time he was not voiding urine oftener than every two or three hours and without pain, but it was often involuntary. There then began some exacerbation of the kidney inflammation, the specimen showing 5 per cent. albumin, urea 1.6 per cent., and numerous casts of all kinds. The patient was very restless and incoherent. The eyes were still swollen, but this caused no anxiety. Blood examination: hemoglobin 78 per cent., red cells 4,544,000, leucocytes 8,400, blood plates numerous, clot formation delayed, alkalinity 239 Mg. per 100 c.c. calculated as NaCH (diminished). No nucleated reds, numerous poikilocytes. Differential count: Polynuclear neutrophiles 73 per cent., lymphocytes 13 per cent., mononuclears 5 per cent., eosinophiles 6 per cent., transitionals 3 per cent. Dr. Brooks remarked:

"It is to be noted that there is no leucocytosis, which is usually pronounced in well-marked cases of pyelitis and cystitis. The increase in the eosinophiles may be due to gastrointestinal disturbance."

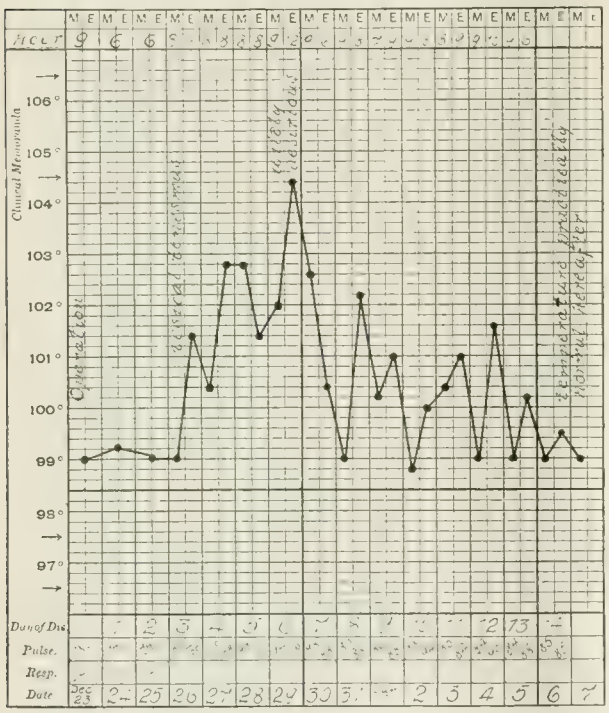
The condition remained practically unchanged until February 4, the forty-third day after the operation. The urine, which was never decreased in quantity, habitually contained 5 per cent of albumin and innumerable casts, with pus and mucus. The mind occasionally showed glimmers of intelligence, but these periods were rare; there was no sleep without large doses of hypnotics, and restlessness was distressing. Talking was incessant and incoherent. Micturition and defecation were often involuntary. The frequency of the former was much improved, the urine being retained about three hours and its passage being unattended with pain. The eyes had improved for a time with the improvement in the kidneys, but with the increase in the albumin and other elements, the edema returned, and with this began a superficial ulceration of the cornea under the upper lids, which caused grave concern. Encouragement, however, was derived from an examination of the fundus of the eyes under homatropine solution. No abnormality of the retinæ, optic discs, or blood-vessels was found. The cerebral excitation was thought to be due to colon bacillus toxemia rather than to faulty excretion from the kidneys. A culture of the urine again on February 4, the forty-third day, showed colon bacilli in large numbers. The patient's general condition was rapidly deteriorating. Exhaustion and weakness were becoming pronounced, and emaciation was steadily increasing. On February 9, improvement took place in the urine. The albumin had decreased to a trace, casts were less numerous, and the pus cells were present in small numbers. The ulceration under appropriate treatment now disappeared from the eyes and left no trace, and the edema of the conjunctivæ and lids was almost gone. Dr. Brooks remarked that "the evidence in the kidneys of a suppurative process had markedly declined." There was some slight improvement in the mental symptoms, but the patient was still irrational most of the time. On February 23, the sixty-second day after the operation, there began an exacerbation of the symptoms again. The urine was acid, 1022, albumin 10 per cent., excess of indican, urea 1.4 per cent., very numerous casts of all kinds, and many pus cells. Acetone and diacetic acids absent. Cerebral excitement was increased. February 28, albumin 15 per cent., and "evidences that the kidney parenchyma was becoming more involved." The patient refused food and medication, and was wildly delirious. Urine and feces always passed involuntarily, the former about every four hours. For the past few days and nights there had been intervals of Cheyne-Stokes breathing. The conjunctival tissues became enormously swollen so that they protruded between the lids. The conditions were alarming. On March 1, the sixty-eighth day after the operation, at 6 A.M., there was a failing of the pulse which required vigorous stimulation. The cerebral condition was one of apathy, but no coma. At 8 P.M. the temperature was 102.8° and the pulse 160 and bad. A hypodermoclysis was given of a quart of salt solution. This was repeated the next morning, and as a result the pulse was much improved and it remained so. March 2, temperature 102.4°, pulse 105. The patient was wildly delirious. Very free catharsis was now administered with the hope of getting rid of some of the poison, which was evidently very powerful. March 3, the seventy-first day after the operation, albumin 5 per cent., urea 2.7 per cent., excessive indican, numerous casts and pus cells. March 10, albumin 10 per cent. The patient was semi-rational for the first time on this day, the seventy-eighth day after the operation, for a short while. One of the puncture points for the hypodermoclysis showed an abscess, which was opened. Culture from this showed no colon bacilli, but *Staphylococcus epidermidis albus*. On March 13, the patient became conscious and remained so for four days. Evidence of colitis, diarrheal movements, with mucus and slight traces of blood. March 14, albumin 4 per cent., casts less numerous. March 18 and 19, irrational again. March 20, the eighty-seventh day after the operation, urine negative as to albumin with Heller's test, faint trace with Esbach's. Very marked decrease in the number of casts and pus cells. The patient was perfectly rational, but mentally excessively depressed; he would not speak, and often wept. Culture of urine showed still the presence of some colon bacilli, that is, eighty-eight days after the operation.

On March 23, the ninety-first day after the operation, the patient was perfectly conscious for the whole twenty-four hours for the first time. Urine acid, 1017, minute trace of albumin, excessive indican, urea 1.7 per cent., numerous casts, and a few pus cells. There was marked mental depression; the patient was hungry; he was emaciated to a skeleton, and suffered pitiable physical weakness, being unable to move himself in the bed; the eyes were normal.

From this time, however, the patient went on to make an uninterrupted recovery. A colitis of moderate severity caused some discomfort, but came easily under control. On March 30, urine 1012, clear, acid, no albumin with Heller's, minute trace with Esbach's test, urea 1 per cent., normal indican, a few hyaline and finely granular occasional epitheliated, rarely small, fatty casts, also an occasional leucocyte. Urinates about seven times in the twenty-four hours and can hold as much as seven ounces at a time in his bladder without discomfort. April 1, the ninety-ninth day after operation, culture of the urine showed the *absence* of colon bacilli. April 12, the patient sat up in a chair for the first time for half an hour. Extreme weakness. Urine 1016, clear, acid, no albumin with Heller's, minute trace with Esbach's test, urea 1.4 per cent., excessive indican, small number of small hyaline and finely granular casts, an occasional pus cell, and a few large uric acid crystals. April 27, examination of the urine gave the same results as on April 12. The patient was gaining strength very fast; mental depression and hebetude still continued. May 13, he went into the country. He was very emaciated, but could walk up one flight of stairs. He urinated about seven times in the twenty-four hours, without discomfort. Bowels a little irregular and some pain on defecation in the rectum, in the region of the operation. May 27, urine 1018, acid, clear, no albumin with Heller's, minute trace with Esbach's test, urea 1.7 per cent., excessive indican, numerous small hyaline and fine granular, occasional epitheliated casts, and a few isolated leucocytes. The patient eats, sleeps, and feels well. Flesh and strength rapidly returning. June 15, examination of the urine gives the same particulars as the last.

Physical examination of the patient at no time elicited any enlargement or tenderness of either kidney. The liver and spleen never were enlarged nor tender. There were no lung symptoms at any time, and the pulse throughout ranged from 80 to 90, except once for twenty-four hours, when there was a dangerous attack of cardiac failure which

nearly cost the patient his life. The urine at no time was diminished in amount, and there was no hematuria. The urea approximated the normal in amount. Albumin varied from a strong trace to 25 per cent. There was habitually an excessive amount of indican present, as well as an enormous number of pus cells and casts of all kinds. At times there was some decrease in the excretion of the solids. The most prominent symptom was the wild delirium which was always present with very slight intermissions, and lasted for practically eighty-five days. It was an active, busy delirium, attended by great restlessness and incessant bodily motion. It was certain that some powerful cerebral irritant was acting. No sleep was obtained except under the influence of massive doses of hypnotics. There never was any vomiting, and the stomach throughout maintained its functions perfectly. The bowels were inclined to be loose in the later stages of the disease, due to the previous colitis, while at first there was some tendency to sluggishness, easily relieved by enemata. Tympanites never was troublesome. There was not



the slightest evidence at any time of any edema of the body except that in the eyelids, which was probably due to a local infection. The first symptom was excessive vesical tenesmus and some rise in temperature on the third day after the operation. On the sixth day the temperature rose to 104.4°, following which it gradually declined to the normal, which it reached on the fifteenth day. The temperature continued normal throughout the remainder of the sickness except for some slight occasional rises. Urination continued frequent for about three weeks, when it became normal and remained so thereafter. Cultures showed that the urine contained pure growths of colon bacilli for about ninety-five days.

The etiology of the infection is somewhat uncertain, and opinions on this point have varied widely. There seems to be no way of clearing up the uncertainty. The catheter will be blamed at once by possibly the majority of physicians. Personally, I do not believe that this was the mode of entry of the bacilli, for all precautions were taken which could have been taken. The following seems to me to be a perfectly rational explanation: The man had had a diseased intestinal canal for some time, and, from what has been already said in the introduction, we may assume that the colon bacilli in his intestines were not only more numerous, but were also much more virulent than is normally the case. From the raw areas on the anterior surface of the rectum colon bacilli passed into the lymphatics of the perineum and thence into the bladder, from which they ascended, either by way of the ureters or by the lymphatics of the ureters, into the pelves and bodies of the kidneys. This ascending infection must have been a very rapid process, for the kidneys were severely involved four days after the onset of urinary disturbances. Another way in which this infection may have arisen is that the bacilli were absorbed from the rectal wounds directly into the general circulation, and the kidneys, in excreting them, were themselves infected, and descending infection of the bladder followed.

The prognosis as to permanent recovery from the ill effects of such a severe lesion of such important organs as the kidneys would seem to be poor. One would naturally expect permanent, serious changes in the kidney. This man, however, has regained perfect health in every way. He has no more frequent micturition than before the operation. The urine on February 12, 1906, ten months after convalescence began, is perfectly clear, acid, sp. gr. 1012; it is negative to each of the albumin bodies of serum albumin, nucleoproteid, serum globulin, and albumose, no casts, a few mucus cylindroids, no pus. His convalescence lasted four months, but his restoration to health has been perfect in every way.

The treatment of this patient presents certain points of interest. It was recognized early that the process was one of infection of the urinary tract, with severe systemic poisoning from colon bacillus toxins, rather than from defective excretion by the kidneys. The bladder was irrigated twice a day with 1-1,000 solution of permanganate of potassium, each irrigation being continued until the solution came away clear. Marked benefit of the vesical symptoms was quickly accomplished with this treatment. To combat the infection in the kidneys, sixty to eighty grains of hexamethylenamine (urotropin) combined with twenty to thirty grains of benzoate of sodium, were administered in divided doses in the twenty-four hours with large draughts of water. At no time did the urine become alkaline. Large doses of hypnotics were required to gain some rest for the patient. The most efficient combination was found to be ten to twenty grains of sulphonethylmethan (trional), combined with fifteen grains of chloralformamid (chloralamid), supplemented by half-grain doses of codeine, either by mouth or by hypodermic, repeated as often as necessary to effect the purpose, sometimes no less than three or four grains of the latter being given of necessity in a few hours.

Great difficulty was experienced in getting the patient to take any medication, as he had a fixed delusion that he was being poisoned. Rectal enemata of salt solution, although strongly indicated, on account of the tenderness in the rectum, provoked such a contest that they had to be abandoned. Milk in large quantities was well taken and well borne. Free catharsis was maintained by castor oil and proved very beneficial upon the cerebral condition. Disinfection of the intestinal tract was attempted by salol at first, but later izal oil (one of the cresols) was substituted with marked benefit.

In treating urinary infections it will be admitted at once that we must make the urine as antiseptic as possible. Probably the best agent that we have is hexamethylenamine (urotropin). This when administered by the mouth is broken up into ammonia and formaldehyde gas, which latter is thus liberated in the urine, and to which its antiseptic properties are due. It is my feeling, however, that large enough doses are not ordinarily administered in urinary infections, and I base this opinion on the following: Dudgeon (*Lancet*, January 20, 1906, page 159) reported experiments with solutions of this drug. He made these solutions with a broth medium in strengths of 0.1, 0.5, and 1 per cent. He obtained constant results with cultures in these solutions. Typhoid bacilli grew well in the 0.1 per cent. solutions, fairly well in 0.5 per cent. solutions, and there was no growth with 1 per cent. solutions. Colon bacilli from peritonitis and cystitis gave abundant growths in 0.1 and 0.5 per cent. solutions, and a fair growth in 1 per cent. solutions.

If these experiments are correct, then possibly we may be allowed the following line of argument: Basing the average amount of urine passed in twenty-four hours as fifty ounces, to produce a 1 per cent. solution with this amount of urine, it would be necessary to administer 250 grains of hexamethylenamine (urotropin) in the twenty-four hours. According to the above experiments, even with this amount we would be merely inhibiting somewhat the multiplication of the organisms. Certainly in most cases even half this amount could scarcely be given, for, while the drug does not disturb the stomach, at times it seems to produce vesical irritation (Keyes, also *Lancet*, December 9, 1905, page 1686), which is always the signal to decrease or temporarily discontinue the drug. At times it has produced hematuria, and in a few cases renal colic. The drug seems to act best in acute infections, and is of much less value in chronic cases. It is best to administer it tentatively in small doses at first, five grains every four or six hours, and to push it as rapidly as possible to fifteen or twenty grains every four hours. A convenient way to administer it is to dissolve the total amount to be given in the twenty-four hours in a quart of water, and in this way whenever the patient takes a drink of water some of the remedy will necessarily be administered.

If the urine be alkaline, it should be rendered acid by giving acid sodium phosphate, benzoate of sodium, boracic or benzoic acids, and when the urine is acid, it is best to make it alkaline by administering bicarbonate of sodium, or the citrate, acetate, or bitartrate of potassium (or all three in combination), because the urea-decomposing organisms have their growths hindered by an excess of acid, while the microorganisms which retain the acidity of the urine, or render it still more acid, are inhibited in their growth by an alkaline condition of the urine.

It must always be borne in mind that, if there be rebellious or recurring infections of the urinary tract, caused by absorption of colon bacilli as a result of enterocolitis, constipation, etc., there will be no cure of the urinary symptoms until the intestinal condition is overcome, to effect which a milk diet, intestinal antiseptics, colon lavage, etc., may be necessary.

50 East Fifty-third Street.

Cracked Pot Sound.—Mangolt says that this phenomenon may be elicited over the abdomen in conditions in which there is narrowing of the lumen of the gut through pressure, kinking, etc.

ALBUMINURIA: RECOGNITION OF THE ALBUMIN-BODIES IN URINE.*

By T. W. HASTINGS, M.D.,

New York,

Cornell University Medical College.

The term "albuminuria" is loosely used for the presence of any albumin-body, occurring in the urine, which responds to the tests for albuminous material. One may see at once, in looking over the subject of albumins and in considering the albumin-bodies existent in the human organism and their physiology, that it is possible to have in the urine several kinds of albumin-bodies dependent upon various conditions, and, further, if one take care to search for these various bodies they can be proven in many urines. During the last year and a half we have found, in going over the daily urine examinations carefully, most frequently serum-albumin and "nucleo-albumin" and the "mucin-like body," less frequently serum-globulin and fibrin and fibrinogen; histons we have not been able to demonstrate even when the urine was rich in hemoglobin and we have not found Bence-Jones albumin-body. The traces of digestive albumose (deutero-albumose), which occur not infrequently in urines, and peptone are not here considered since they do not respond to the usual tests for albumin (excepting Esbach's reagent) and have not the significance of the native albumins and proteids (Conheim's classification). Furthermore, the two bodies responding to the test for "nucleo-albumin," viz., nucleo-proteid of cell nuclei and "nucleo-albumin" (phosphorus-holding albumin), we have not attempted to separate, and the positive nucleo-albumin reaction apparently is of little or no significance; yet it must be recognized that such reactions may be readily confused with the slight reactions for serum-albumin when the ordinary tests are used, as we have demonstrated repeatedly with nitric acid, and heat plus nitric or acetic acid. Recognizing the valuelessness attached to positive nucleo-albumin reactions, the testing for albumin resolves itself into this — to employ a method which will rule out nucleo-albumin and at the same time show any trace of serum-albumin, serum-globulin, fibrin, fibrinogen and Bence-Jones albumin. The albuminuria following excessive ingestion of egg-albumin will not be considered, since its source is wholly exogenous and the condition is not related to the subject under consideration.

Theoretically the consideration of the various albumin-bodies possibly coming under the term "albumin in the urine" leads one into the study of a rather bewildering number of products having origin in or from the body tissues and a still more bewildering mass of chemical tests for these products.

The following outline has been divided into the albumin-bodies (1) occurring in the urine and (2) those uncertain and not considered.

(1) Albumin-bodies occurring in the urine:

a.—True albumins:

- Serum-albumin.
- Serum-globulin.
- Fibrinogen and fibrin.
- Nucleo-albumin.
- Bence-Jones albumin.
- Albumin from bacteria and vegetable cells.

*Read at a meeting of the Section in Medicine of the New York Academy of Medicine, March 29, 1906.

b.—Proteids:

Nucleo-proteids.
Hemoglobin.
Methemaglobin.

Hematin... } Derivatives of hemoglobin, not proteid, but thrown out of solution by acetic acid.
Hematoporphyrin...

Glyco-proteids:
Mucin.

Arising from albumin-bodies and related to them—

Give biuret. [Urobilin also gives a biuret color with $CuSO_4$ and NaOH.]

Albuminoses: Precip. with "salting" and acid; sol. in heat, reappearing on cooling.
Primary albumoses. } Not found in urine?
Hetero-albumoses.. }
Proto-albumoses... }
Deutero-albumose: Frequently found in traces.
Peptone: No response to "salting" and heat and acid.

(2) Uncertain and not classified:

a.—Cell-globulin:
"Harn-globulin" (= urine-globulin). Huppert says is hetero-albumose.

Histon; as globin in hemaglobin, particularly. Does not occur free, but with a prosthetic group as in Hb or with nucleo-proteid. Thrown out by ammonia and dissolved in excess; as albumose with HNO_3 cold, and heat; readily digested by pepsin and trypsin, not by erepsin.

Protamine; not in urine (unless possibly from tubercle bacilli or from the albumin radicle of nucleo-proteid); not thrown out by heat.

b.—Proteids. "Harn-mucoid," stands near mucin and acts as does mucin; forms the "nubecula," says Mörner (Conheim, p. 280).

c.—Albuminoids. Melanine; does not give usual albumin reactions (Conheim, p. 309).

For convenience the following headings under A (I and II), B, and C, may be made relating to the condition giving rise to albuminuria, detection of albuminuria, and the usual relation to faint and massive reactions to albumin-bodies found.

A.—Albumin-bodies in the urine may arise (I) from normal tissue, or through impairment of tissues along the genitourinary tract; the renal function is not disturbed; (II) not from the genitourinary tract, but from the blood-stream, lymph. through (*a*) normal or not necessarily impaired renal tissues (as a "foreign albumin"), or (*b*) through impaired renal tissues.

B.—Tests, and reasons for "salting" and acetic acid and heat test.

C.—Separation into (*a*) frequency of occurrence and (*b*) faint and massive reactions.

A. I.—Albumin-bodies from normal tissues, or through impairment of tissues along the genitourinary tract; not nephritic: mucin, nucleo-albumin, nucleo-proteid, serum-albumin, serum-globulin, fibrinogen, fibrin, hemoglobin and derivatives.

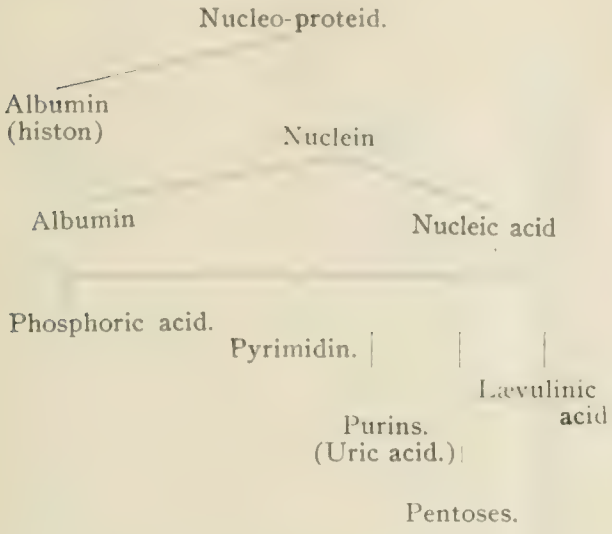
We shall consider, first, the various albumin-bodies which may arise from the normal tissues or through some impairment of tissues along the genitourinary tract with no disturbance of renal function; from the renal tissue and the cystic mucous membrane and in the male from other neighboring sources, as the prostate and reproductive glands, the "mucinlike" body, which in part forms the "nubecula" found in most urines on standing, is apparently thrown off under normal conditions whether as a secretion from the surface cells or from between the cells or from just what source is not known, and for practical purposes this body may be passed over, for it can scarcely be confused with other products since the response to ordinary tests is markedly different.

It is to be noted, however, that this "mucin" reacts in dilute solutions poor in neutral salts, after overacidulation in the cold, as does the nucleo-albumin, to be mentioned later. The large amounts of mucous material mingled with pus found in certain conditions of inflammation are probably not of the same composition as this "nubecula" mucin, and this again does not concern us, for the albumin-bodies in such gross inflammatory conditions are not of diagnostic importance. A mucoid nucleo-albumin is recognized as found in solution in the semen composed of testicular and prostatic and the allied gland secretions and an albumose-like body in solution, described by Posner as from the prostate, has not been recognized by other investigators. Thus, the proteids in solution in the semen may be classed, so far as we know, with the mucin-like bodies and the nucleo-albumin which may occur in the urine under normal conditions.

Whether the "nucleo-albumin" found so frequently under apparently normal conditions has any significance remains to be determined. According to Halliburton and Lilienfeld a nucleo-albumin is to be found in renal cells, and one frequently finds a substance responding to the tests for nucleo-albumin in the urine. It has been suggested that such an albumin-body is thrown off into the urine when the renal tissue is under "irritation"—an indefinite statement of little significance so far as we know to-day. Whether its source be renal, cystic, prostatic, testicular, or urethral, this body is of importance to us, from the fact that we find it alone responding to the tests for albumin, as a faint reaction (a "trace") in 30 per cent. of our examinations, and therefore one should take care to rule out this reaction before concluding in regard to the presence or absence of a pathological "albumin-body."

The nucleo-proteids which are so abundant in glandular organs and which may arise from the nuclei of pus corpuscles, for example in a case of pyuria, are quite distinct, in composition and in disintegration products, from this nucleo-albumin, although the reactions of both to the organic acids in dilute solutions poor in neutral salts are the

same. From the consideration of the digestion of nucleo-proteids from food stuffs—



it does not seem possible that there could be an exogenous source for urinary nucleo-proteids, and provided this be so, the nucleo-proteid from nuclei of the pus corpuscles would be found in the urine under inflammatory conditions only, in which conditions other more important and more easily detected albumin-bodies are present, such as serum-albumin, and therefore the nucleo-proteid may be neglected.

The forms of albumin with which nucleic acid and nuclein are bound to form nucleo-proteids are histon and protamine, so far as known, and thus theoretically, the nucleo-proteids of food stuffs might be a source of histon and protamine in urine, but so little is known in regard to these bodies (histon and protamine) as related to food-stuffs that it is impossible to consider them.

Whether or not such true albumins as serum-albumin and serum-globulin occur in minute amounts in normal urine need not disturb us, for under normal conditions there is not a sufficiently large amount of such a body to react to the tests used ordinarily for the detection of "albumin." Bearing in mind that we are still considering the "albuminuria" of normal tissues or of locally impaired tissues of the genitourinary tract, not coming under the term "nephritic" as the term is usually understood, we may consider the causes of the condition under four divisions, viz.: (1) infectious, with exudation; (2) congestive, with transudation; (3) traumatic, with hemorrhage or exudation and diapedesis; (4) neoplastic, with hemorrhage or exudation and diapedesis, any one of which general conditions may produce an albuminuria, consisting of the presence in the urine of serum-albumin alone or with serum-globulin, fibrinogen or fibrin, bodies which may be found in a nephritic's urine, but in the nonnephritic cases the urines are usually cloudy, contain pus and blood cells and in other respects the specimens are unlike the urines of nephritis (excepting acute nephritis) and, most important of all, the clinical manifestations are quite different from those of nephritis.

It is a fact that in these nonnephritic conditions nucleo-albumin is usually present with serum-albumin, and it should be emphasized that while the former may come from cell-disintegration, the latter (serum-albumin) is a part of the exudate and is derived from blood-plasma and not from cells, which is contrary to the current idea that in a urine containing "pus cells" in small or large amount the "albumin" comes from the pus cells. In a woman's urine the source of the trace of "albumin," as also of the squamous cells and leucocytes found, is often vaginal. The urine of chronic nephritis rarely contains nucleo-albumin, as a rule serum-albumin alone: the urine of acute and subacute nephritis frequently contains both.

Bacteria.—A source of error must be recognized in urines which have been standing and have collected from the air bacteria. We have repeatedly sterilized non-albuminous urines, infected one-half of the sterilized portion with typhoid, colon, or lactis aerogenes bacilli, and noted the appearance of an albumin-body acting like serum-albumin in "salted," heated, and acidified solutions, particularly when all or a part of the bacteria are killed by heating above 65° C. for ten minutes and this heated suspension of bacteria in urine is allowed to stand for a second period of twelve hours. The process suggested is that of autolysis and the liberation of an albumin-like body from the dead disintegrating bacilli.

A. II.—Albumin-bodies from blood-stream, or lymph, (*a*) through normal or not necessarily impaired renal tissue; Bence-Jones albumin, melanin, or melanogen, hemoglobin, methemoglobin, digestive albumoses, peptones; albumin-bodies from the blood-plasma in conditions with "impoverished" blood in cachexia and anemia, and in chyluria with fibrinuria and fibrinogenuria. (*b*) Through temporary or permanent impairment of the functions of the renal tissue: serum-albumin, serum-globulin, fibrinogen.

A. II.—Albumin-bodies not from genitourinary tract tissue, but from other sources carried by the blood (or lymph?) to renal tissues; (*a*) secreted in the urine through renal tissue not necessarily impaired in function or normal are among the rarest cases of albuminuria—such as the albuminoid melanin or its urinary counterpart melanogen, Bence-Jones albumin ("albumosuria"), hemoglobin, methemoglobin, true peptone—and again some among them are common enough, but unimportant, as the "digestive albumoses" ("peptone"). Probably here should be placed also the cases of albuminuria in many cachexias and anemias in which the "impoverished" blood is supposed to bear a causal relation to the urinary condition.

In the rarer conditions of hemoglobinuria, methemoglobinuria, and hematoporphyrinuria one finds serum-albumin and maybe serum-globulin, and yet from other considerations one will not confuse them with nephritis; and other such true-albumins as histon, and its type globin from hemoglobin, and albuminoids as melanin need not be considered separately, since they are accompanied by demonstrable traces of serum-albumin, and their separation and identification are obtained by methods and reactions not likely to lead to confusion with other albumin-bodies.

Bence-Jones albumosuria is the only one of this group necessary to consider in testing for albumin. In the condition known as Bence-Jones "albumosuria" the albumin-body has its origin in the bone marrow, is carried to the kidneys by the blood-stream, and is excreted in the urine, whether with impairment or none of the renal tissues is not definitely known, and such impairment does not seem necessary, since albumin-bodies "foreign" to the plasma of circulating blood are known to be excreted by *normal* renal tissues. Achard and Gaillard emphasized this fact in 1901,

when they determined by experiment that the *diseased* kidney is more permeable to the albumins "foreign" to blood plasma, as casein, than the normal kidney, and proposed the intravenous injections of casein together with hypodermic injections of methylene blue as a method for testing the permeability of a contracted kidney, the casein output in the urine being greater than normal, and the crystalloid (methylene blue) output being less than normal if the renal condition is that of a contracted kidney. Moreover, these observers found experimentally in dogs that when the renal tissues were called upon to eliminate an albumin "foreign" to the blood plasma (as casein), serum-albumin also passed through the normal renal tissues and that the albuminuria is increased in amount when the damaged kidney is called upon to excrete such "foreign" albumins (as casein). (*b*) Most important is the group in which the albumin bodies of the blood-plasma are excreted in the urine through temporary or permanent impairment of the functions of renal tissue. The body most frequently found under such conditions is serum-albumin, usually with casts, and maybe with serum-globulin; fibrinogen and fibrin may be present also, and under such circumstances the albuminuria is supposedly the consequence of an impairment of renal function leading to increased permeability of the glomerular and tubular tissues. In acute and subacute conditions exudation plays a part, but in the chronic nephritic lesions exudation, in the sense of "exudate from an inflammatory condition," is wanting and the albuminuria has its source from the blood, the albumin passing to the urine in consequence of an increased permeability of the tissues for "albumin." It seems best to include here also the conditions of "cyclic," "postural," "orthostatic," "intermittent," and "physiological" albuminurias, since there is at least disturbance of renal function if not impairment, congenital or acquired, of renal tissues.

From such considerations one is enabled to eliminate from a large number of albumin-bodies all but four, which should be borne in mind in testing for "albumin," viz., nucleo-albumin, serum-albumin, serum-globulin, Bence-Jones albumin ("albumosuria"). The following may be disregarded: mucin, because it does not respond to the tests to be described below for serum-albumin; fibrinogen and fibrin, because they do not occur without serum-albumin, and the nucleo-proteids, from the pus cell nuclei and histon, and other proteid bodies, for similar reasons. It is well to retain serum-globulin as a body to be recognized, since in a massive albuminuria it should not be confused with Bence-Jones albumin.

B. *Tests.*—The objection to some tests is that they will not throw out a well-marked trace of "albumin" in urines poor in neutral salts, *e.g.* cold nitric acid, as in Heller's test; and other tests throw down peptones and all other albumin-bodies, some mucin, *e.g.* potassium ferrocyanide and acetic acid, and citric and picric acids—in other words, these are too "delicate." But the subject is not so puzzling as it seems if one studies these reactions with such complex fluids as urines.

The tests described for albumin run into a disheartening number, most of them with some peculiar feature to recommend them, and all of them with some objections. One most commonly used, Heller's with cold nitric acid, is to be criticised for two reasons, one that it will produce a positive test with the proper ring at contact with some urines containing nucleo-albumin alone and the high ring reaction mentioned in the text-books is one due to the reaction to the mucin-like body in the urine and not to the nucleo-albumin at times found—and these two bodies, mucin and nucleo-albumin, are distinctly different; and another, which is more important, that it will not show up very distinct amounts of serum-albumin in urines poor in neutral salts. Lieberkühn, Heynsius, Neumeister, Halliburton, and Hewlett were among the first to show the effect of neutral salts in solution upon the precipitation of certain proteids by acids and heat. Purdy emphasized this fact years ago, that urines poor in neutral salts, no matter what the specific gravity, do not react well to acid and heat tests for albumin, and that such urines should be enriched in neutral salt content by addition of sodium chloride before carrying out tests; and along this same line Purdy recommended the potassium ferrocyanide-acetic acid test, which was equivalent to "salting"* the urine, but this test throws down nucleo-albumin as well as other albumin-bodies, which is an objection, as will be seen later. Simon has recommended this "salting" as essential to the precipitation of all the "albumins" in many urines. Conheim is the one investigator who has shown definitely that "salting," overacidulation with acetic acid, and heating thoroughly to boiling are the three simple steps to take in order to detect traces of serum-albumin and to throw down completely the albumins commonly found in the urine.

In this country Emerson has used this method for quantative estimations in nephritic urines, under which circumstances he found the percentage amount of albumin excreted in the urine a good guide to the severity and the progress of the nephritic condition. If one will compare this method of Conheim's with the twenty or thirty other methods suggested and used to date, one will find that traces of serum-albumin may be detected in urines "negative" to the tests in vogue, this occurring in urines poor in neutral salts; and on the other hand one will find negative reactions by this method where heat with addition of mineral or acetic acid and Heller's test give faint positive reactions.

There is no use in noting in detail the many tests for albumin-bodies, since trial of many of them and the examination of some 5,000 urines has led to the recommendation for few reasons of one of the simplest—that of adding to the urine to be tested one-fifth to one-sixth its volume of saturated sodium chloride solution (30 per cent. aqueous solution), heating the upper portion of the tube, adding 3 to 5 drops of 50 per cent. acetic acid, and heating a second time to boiling.

C.—Separation of albumin-bodies in urine according to (*a*) frequency of occurrence and (*b*) faint and massive reactions.

a.—Turning to the bodies of import in diagnosis —those which should be and can be readily differentiated—they may be placed in order as follows, according to their frequency of occurrence, judging from some 5,000 urine examinations; naturally the order would vary with climate, country, and surroundings; for example, fibrinuria and fibrinogenuria and hematuria would be much more frequent in tropical countries, where parasitic invasions, such as filiariasis and hematobiasis (Bilharzia) are endemic and common. With us the frequency of occurrence is as follows: Nucleo-al-

*The term "salting" will be used in reference to the ddition of a saturated aqueous solution of sodium chloride (30 per cent.) to the urine.

bumin, serum-albumin, serum-globulin, fibrinogen and fibrin, albumose (Bence-Jones albumin).

b.—Again, they may be divided for sake of convenience in testing into those which respond with "faint" or "slight" reactions (and the term "reaction is used and emphasized purposely instead of the word "amount") to the "salting," heat and acid test, and those which respond with massive reactions to the same tests. Faint reactions: serum-albumin, nucleo-albumin [deutero-albumose (disappears after acidulation)].

Massive reactions: serum-globulin with serum-albumin, serum-albumin alone, fibrinogen and fibrin, Bence-Jones albumin.

Since "salting" the urine not only brings out the serum-albumin in a urine poor in neutral salts, but also holds in solution the nucleo-albumin which may be thrown out by heat and acid in a urine with a poor neutral salt content, these two facts may be combined with two other very simple tests, requiring only heat, saturated "salt" (sodium chloride) solution (30 per cent. aqueous), 50 per cent. acetic acid, and distilled water to make possible the ready separation of nucleo-albumin, serum-albumin, serum-globulin, and Bence-Jones albumin, as outlined in the following:

Tests for albumin-bodies in the urine:

Test-tube 2-3 full of urine. Heat upper one-third of urine; cloudiness may be

Nucleo-albumin... Serum-albumin... Serum-globulin...	Addition of 2-5 drops of 50 per cent. acetic acid and second heating = increased cloud or lessened cloud persisting.
Albumose (Bence-Jones) Phosphates Carbonates	Addition of 2-5 drops of appearance of cloud or and second heating, dis- 50 per cent. acetic acid partial clearing.

If reaction is faint ("faint trace"), probably serum-albumin or nucleo-albumin, or both:

Presence of nucleo-albumin tested for by diluting 3 to 5 c.c. of urine with five to six times its volume of distilled water, adding to one-half of this diluted urine 1 to 2 c.c. of 50 per cent. acetic acid *cold*, not heating: a diffuse cloudiness in the acidulated one-half is nucleo-albumin (may be mucin, but mucin will not respond to first heat and acetic acid test).

Nucleo-albumin is not precipitated by heat and acid in highly "salted" urines: to prove serum-albumin, therefore, to the urine add 1-5 volume of saturated sodium chloride solution, heat upper one-third, add 2-5 drops of 50 per cent. acetic acid, heat a second time: a persistent cloud equals serum-albumin. May be with serum-globulin.)

If a massive reaction, usually serum-albumin with serum-globulin, may be albumose (Bence-Jones), may be serum-albumin alone or with fibrinogen.

To separate serum-globulin and albumose (Bence-Jones): To the urine add 1-5 volume of saturated sodium chloride solution and 2-5 drops of 50 per cent. acetic acid, without heating = cloudiness, may be serum-globulin or albumose (Bence-Jones) (rarely serum-albumin alone).

*Digestive albumose not uncommonly occurs as a faint reaction, but does not persist with heat and acid (acetic) tests, so will not be confused with faint reaction for serum-albumin; true peptone does not respond to heat and acid.

Heat upper one-third = heavy cloud followed by partial clearing suggests albumose (Bence-Jones) = persisting cloud is serum-globulin, or serum-albumin, or both. Boil entire tube, filter, heavy cloud reappearing in filtrate on cooling = albumose (Bence-Jones). A faint reaction on cooling, due to deutero-albumose, often appears, and this has practically no clinical value.

For serum-globulin.—To a test tube of distilled water add urine drop by drop to 8 or 10 drops, no heating, a cloud (cold) = serum-globulin, which clears after addition of 2 to 5 drops of 50 per cent. acetic acid (cold).

Recently we have followed the urines of pneumonia cases in respect to the chlorides, as the type of neutral salt most abundant in urine, and the albumin reactions, and have found as one would expect, that marked reactions may be checked by the low salt content of the urine which develops during the course of the disease, and yet one cannot say that the one depends absolutely on the other, although low salt content and a checked albumin reaction do occur in the same specimens. Such facts suggest that the condition of the renal tissues as evidenced by the urine albumin-content is not to be followed accurately unless one makes allowance for this poor salt content and "salts" the urine before testing with heat and acetic acid. And this statement holds, also, for the many cases of chronic nephritis in which the specific gravity is low and the percentage salt content poor, for the absolute amount of neutral salt excreted in twenty-four hours is not of import, but the percentage neutral salt content in any one specimen, in its influence upon the albumin reaction.

When the sodium chloride content, in pneumonia, is below 0.4 per cent. to 0.5 per cent., the albumin reaction in "unsalted" urines may be quite misleading.

In routine urine examinations errors are apt to occur with urines containing small but well-marked amounts of albumin, and one should be cautious in respect to faint albumin reactions which may be due to nucleo-albumin, and in respect to the trace of serum-albumin which is not readily thrown down in urines poor in neutral salts: and it is well to state that such errors may be avoided by making use of this one test for albumin, viz., that of "salting" the urine by addition of saturated salt solution, acidulating with 5 to 10 drops of 50 per cent. acetic acid, and heating to boiling the upper one-third of the tube. Under such conditions a positive reaction is due to the presence of a pathologic albumin-body. If this test is carried out as a routine one will sooner or later be surprised to find how much less variable and more satisfactory are results than those obtained by the older methods of testing for "albumin."

Conclusions.

1. Many of the albumin-bodies which theoretically might occur in urine may be excluded from consideration for various reasons: serum-albumin, nucleo-albumin, serum-globulin, and Bence-Jones albumose should be considered.

2. For purposes of excluding false reactions due to bacterial disintegration the urine should be examined within six hours after voiding, unless the reaction is massive.

3. The most reliable test for serum-albumin in urine is that of "salting" the urine with a saturated solution of "salt" (sodium chloride), acidulating with 50 per cent. acetic acid, and heating to

boiling; this throws down all traces of serum-albumin and prevents a nucleo-albumin reaction.

Trachoma and Its Treatment.—Cornelius Williams declares that trachoma flourishes in any place in which there is crowding and lack of cleanliness. This disease is looked upon by the greater number of physicians with indifference. Trachoma with and without treatment may last for fifty or seventy-five years. It may in some cases get well of itself in a shorter time. The writer condemns the application of crystal of copper sulphate in the treatment of this affection. He has had a very extensive experience in the treatment of trachoma. He prefers the silver nitrate method, since it has given better results in his experience than any other remedy. This method is attended by no pain. Neither is any lesion of the tissue induced. The microorganism of trachoma is destroyed, and the disease in time is cured. He believes it advisable to suspend the use of the silver salt now and then, for a few days, substituting for it a very weak solution of iodine in the normal saline solution, with the addition of iodide of potassium. Cleanliness is an absolute essential in the treatment of trachoma.—*The St. Paul Medical Journal.*

The Psychology of Disease.—Mary M. H. Johnstone emphasizes the fascination of the study of this subject. She speaks of the condition of euphoria which has been noted in the development of general peritonitis during the puerperium, contrasting this with the anxiety displayed by patients suffering from perforative peritonitis. The difference, says the writer, is simply one of degree in intoxication. The cases with delirium tremens are overmastered by fear. The patient with carcinoma conceals her disease. The alcoholic displays various interesting mental states. Certain toxins pick out special organs or groups of nerves. It would seem that each toxin and antitoxin has its special action upon the psychic cells, causing in one case marked irritability, in others hopefulness, fear, or despondency. The writer concludes by declaring that the practical bearing of all this is that a better knowledge of the physiology and physiological chemistry of cells, especially of psychic cells, is needed. The pathology of cells should be studied, their reaction under different abnormal physiological conditions, and to different chemical stimuli. Each patient should be made a special study as to diagnosis and therapeutics from the psychical as well as the physical point of view.—*The Woman's Medical Journal.*

A Method of Estimating the Opsonic Content of Blood and Other Fluids.—Charles E. Simon and R. V. Lamar, in the course of their experiments, have ascertained that human leucocytes, when washed with normal salt solution containing 0.1 per cent. of ammonium oxalate, promptly lose their phagocytic power, but that this can be restored by the subsequent addition of normal serum. They describe, as follows, the method by which it is possible to obtain non-phagocyting leucocytes in sufficient quantity for all ordinary purposes in a very convenient manner and with the least expenditure of time. To this end the blood is obtained from the finger or the lobe of the ear, as in ordinary clinical work. Approximately 0.5 c.c. is drawn up into a calibrated tube, transferred to a washing tube of 0.5 cm. diameter, mixed with an excess of normal salt solution containing 0.1 per cent. of oxalate, and centrifugalized. When the corpuscles have been well packed, the supernatant fluid is twice replaced by normal salt solution, the tube inverted a few times, and again centrifugalized. The leucocytes after this are devoid of phagocytic action, and ready for use, when it is desired to determine the opsonic content of the second specimen of blood or other fluids. In the case of the blood a corresponding amount, as in the first instance, is obtained by puncture, placed in a drawn-out tube, and at once centrifugalized, until the corpuscles are firmly packed and the supernatant fluid is clear. With this serum, dilutions are made with normal salt solution in varying proportions. Small tubes are charged with a few drops of diluted serum, inoculated with the microorganisms under consideration, so that a moderate milky turbidity results, further treated with a small quantity of washed corpuscles, and incubated for thirty minutes at 37° C. Smears are finally prepared on slides, and, when air-dry, stained with a strong solution of methylene blue, containing a trace of sodium hydrate. As index of the opsonic content of the blood under examination, the writers then take that degree of dilution at which phagocytosis has practically become extinguished, or when the number of non-phagocyting cells exceeds 90 per cent. This they designate as the opsonic coefficient of extinction. They have thoroughly tested the practical value of the method as just outlined and have every reason to regard it as established.—*Bulletin of the Johns Hopkins Hospital.*

A Plea for a More Prominent Position of Glandular Fever among Infectious Diseases, with a Report of Twelve Cases.—Albert E. Vipond defines glandular fever as an acute infectious disease characterized by an inflammation of the lymph nodes of the anterior and posterior triangles of the neck, generally involving as well the lymphatic nodes of the axilla, and often those of the inguinal region. The writer declares that it is quite impossible to diagnose glandular fever until the lymph nodes become involved. Even then a thorough examination of the throat, mouth, scalp, and so on, must be made in order to exclude any local source of infection. West's ninety-six cases occurred in forty-three families, while four of the writer's twelve cases were found in one family, and two were found in each of two other families. Although this disease does not occur with such frequency as the more common infectious diseases, the writer thinks that it might rank in this respect with rubella.—*Archives of Pediatrics.*

Physiological Action and Indications of Mechanotherapy.—I. Gunzberg tells us that mechanotherapy is largely used and much appreciated at the present day. It consists of the application of movement regulated by therapeutics. It utilizes the force inherent in the muscles, liberates the latent energy, and utilizes all the physiological properties of the reflexes and the elasticity of the tissues. Its action is local and general. By proper dosage fatigue is avoided, while it localizes exercise. It is indicated in paralysis the result of accident, compensated cardiac affections, affections of nutrition, gastrointestinal atony, scoliosis and other deviations of the spinal column. It is also useful in a series of other affections of diverse nature, in which the physical agent, movement, may be applied. The contraindications are few and may be easily found out on examination of the patient. The era of empiricism in mechanotherapeutics is passed. This agent has become indispensable to the clinician. A union of massage and kinesotherapeutics may be of inestimable value in medicine.—*Annali di Elettricita Medica e Terapia Fisica.*

ANKYLOSTOMA INFECTION THROUGH THE SKIN.

SINCE Looss in 1898 made his first observations on the entrance of *Ankylostoma duodenale* into the human body by way of the skin, his work has been repeated and confirmed by Boycott, Tenholt, Bruns, and, in this country, Claude Smith. Looss has not only repeatedly demonstrated the truth of his first announcement, but has further done much toward tracing the exact route taken by the larva on its way from the surface of the body to the intestines. At the present time, therefore, there can be no reasonable doubt as to the correctness of his first observations. The choice of such a roundabout journey for an intestinal parasite had no biological analogy, and while its actual occurrence, in spite of strenuous opposition by Lichtenstein, Grassi, and other authorities, could not be refuted, it was nevertheless regarded for a long time as, at the most, a laboratory curiosity which could not be considered as etiologically important.

Looss himself, soon after his first announcement, studying the habits of the Egyptian farm laborers, a class much afflicted with the disease, expressed the opinion that possibly a very considerable percentage of sufferers were infected in this way. These people do most of their work standing with bare feet in the freshly irrigated fields, ankle deep in the mud, which is one of the best media for the development and preservation of the ankylostoma larvæ. Their habits in regard to the natural necessities are not the most fastidious, and as the stools of many of them contain ova, infection through the skin of the feet and legs seemed more than probable. Additional support for this view was furnished by the frequency with which these laborers suffered from a dermatitis of the feet, similar in many respects to the dermatitis produced in persons experimentally inoculated.

From the report of the United States Commission on Anemia in Porto Rico, it appears that the discovery of Looss will truly play a most important part in the prophylaxis against this disease. The Commission concludes, after a careful analysis of its cases, that, in Porto Rico at least, the infection with ankylostoma is generally contracted by penetration of the larvæ through the skin. It appears that in this island the large majority of the victims to the disease are the unshod farm laborers. During the rainy season they are almost without exception annually attacked by a dermatitis which they know as "mazamorra." Of 284 patients who were found infected with ankylostoma, 263 gave a definite history of "mazamorra," and most of these seemed to trace some connection between the illness from which they were suffering and this initial dermatitis.

Two very striking cases are cited in this report. The first was that of a negro who was employed in digging the latrines for the burial of the infected stools used at the laboratory. Soon after beginning his work this man complained of being "eaten up by mazamorra." Sixteen days later he reported himself too weak to work, and at this time examination of his stools revealed the ova of *Uncinaria* in large numbers. A still more convincing case was that of a soldier who was admitted to the San Juan Hospital suffering with severe mazamorra. He had been employed in cleaning some pits near Morro Castle and had been doing his work barefooted. This man was sent to get some of the mud of the pit which he held responsible for his disease. In this mud larvæ of the parasite were found in abundance.

There seems to be no link missing in the chain of evidence necessary to prove that entrance through the skin is a frequent and dangerous source of infection; and the discovery of this mode of entrance —made almost accidentally by Looss in 1898—now corroborated by many other observers, promises to put the prophylactic measures against ankylostomiasis on an entirely new and simple basis.

THE VOMITING OF PREGNANCY.

WHILE a certain degree of nausea and vomiting is the rule at some stage of pregnancy, the pernicious or fatal type of the disorder is quite uncommon. The difficulty of the situation resides in the fact that one cannot foresee whether or not in any given case the mild form will be converted into the severe. From the existing evidence it would appear that the condition when present is not always due to the same cause, so that the measures of relief to be employed must be varied accordingly. It is important, in the first place, to make a sharp distinction between vomiting occurring incidentally in the course of pregnancy and that which is a direct outcome of pregnancy. As the result of a most comprehensive study of the subject, based upon a thorough survey of the literature and a not inconsiderable personal experience, Dr. J. Whitridge Williams (*Bulletin of the Johns Hopkins Hospital,* March, 1906) differentiates three distinct types of the disorder, namely, reflex, neurotic, and toxemic, in accordance with the varying etiological factors present in the individual case.

Reflex vomiting of pregnancy results from disorders of the generative tract precedent to or coincident with pregnancy, such as abnormalities of the uterus, particularly displacement, endometritis, ovarian tumors, and abnormalities of the ovum, such as hydramnios, hydatidiform mole, or twin pregnancy. The treatment consists in removal of the underlying disturbance; and in the presence of hydramnios and hydatidiform mole the pregnancy should be promptly terminated. The neurotic variety of vomiting of pregnancy is referable to the attendant disturbance of mental, moral, and nervous equilibrium, and it responds most readily to suggestive and supporting treatment.

From the earliest times it has been held that the vomiting of pregnancy is due to the presence of toxic substances of varied origin, and opinions still differ as to the nature and source of these. Such intoxication, it has been thought, may arise from the gastrointestinal tract, from the ovum and its appendages, from ovarian secretion, or from hepatic lesions. Examination of the urine from women suffering from the vomiting of pregnancy often discloses the presence in increased amount of uric acid, indoxyl, syatoxyl, aromatic sulphates, phenol, and nucleoalbumin, and also of acetone, diacetic acid, peptone, urobilin, etc., indicating absorption of toxic materials derived from decomposition of carbohydrates in the stomach and of proteids in the intestine. In another group of cases symptoms of profound derangement of metabolism are present, together with lesions in the liver analogous to those of acute yellow atrophy. The characteristic clinical feature under these conditions is a marked decrease in the amount of nitrogen excreted in the form of urea, together with a marked increase in the amount excreted in the form of ammonia. The treatment consists in prompt evacuation of the contents of the uterus.

THE REAL ENEMIES OF THE AMERICAN MEDICAL ASSOCIATION.

We are informed that an effort is being made by the supporters of those in power in the councils of the American Medical Association to create the impression that the Medical Record, which has not hesitated to criticise their arbitrary and unconstitutional methods, is inspired by enmity to the Association. The charge is ridiculous, but that it should be made by the men who have acquired control of the Association, and who know that the only way to retain their power is to down opposition, is natural. No reader of this journal, however, who is not so blinded by prejudice that he cannot sense what he reads has any excuse for saying or believing that the Medical Record is inimical to the American Medical Association. The editor is a member in good standing of the Association, and every word he has written in criticism of the oligarchy which now rules has been dictated by the sincerest desire to promote the welfare of that great and useful organization. It is a belief shared by many of the best men in the organization, even by members of the House of Delegates, that the worst enemies of the American Medical Association to-day are those who make up the little group that governs the Association, while its truest friends are those who oppose this unpopular rule and are working to save the organization from impending ruin. It is a consciously shaky government that would stifle criticism of its acts; honest governments, like honest men, invite criticism and welcome opposition. The Medical Record and other open critics of "bossism" in the Association are no more enemies of the organization than are the critics of our national rulers traitors to their country.

The American Medical Association is apparently more prosperous to-day than ever before, but this apparent prosperity rests upon a precarious foundation, and the organization is in jeopardy of its very existence as the one great bond of union in the medical profession. There is loudly expressed disaffection with the present management all over the country, from Texas to Michigan and from the Atlantic to the Pacific, disaffection which is assuming definite form in the organization of new State medical societies owing no allegiance to the national body. There is even serious talk of a rival national association. The leaders in this revolt confound the Association with its temporary rulers—a confusion which is shared by these same rulers—but they forget that the great body of the Association is composed of earnest, honest men, caring naught for medical politics and as yet barely awaking to the fact that they are governed by unwise men, who, wittingly or unwittingly, are dragging down the medical profession of the country into the mire of disunion. When once they are fully alive to the dangers which threaten their organization they will be not slow to make a change in methods, if not in men.

A rupture of the Association and the formation of a rival body would be a grievous disaster, for a disunited profession would bring ridicule upon itself and lose what influence it now has in matters of public health. It is in the hope of arousing the members of the Association to a sense of their peril that the Medical Record has assumed the thankless task of criticising the management, exposing its policy of concealment, and condemning its dictatorial methods. It believes the Association can be saved from disruption only by curbing the intemperate zeal of those who now control it. Those men must be made to realize that they are the servants of the Association, not its masters. One or two of them are men of ability, but so much the more dangerous if their talents are employed to further selfish ends rather than in the interests of the American Medical Association, whose creatures they are. The Medical Record claims the right to speak for the Association when the natural protectors of the latter are turned against it; it is they, not we, who are the real enemies of the Association, since it is their acts, not our criticism, which have brought this great body to the brink of disruption.

The Normal Daily Temperature Variation and Its Manifestations in Pulmonary Tuberculosis.

We are accustomed to observe diurnal variation in the normal body temperature in man and in warm blooded animals. In the evening, towards the end of the period of physiological activity, the temperature is higher than it is in the early morning, towards the end of the period of rest. Alteration in the character of the temperature variation is a characteristic of many diseases, but in none of these are its manifestations so varied as in pulmonary tuberculosis. In order to determine what effect modifications of the periods of rest and activity would have, J. J. Galbraith (*Practitioner*, February, 1906) undertook a series of observations on the monkey. This writer found that by reversing the routine of the monkeys' lives—that is, by making them sleep during the day time in a darkened room, and keeping them awake at night by lighting the room with an artificial light, he was able to produce a reversal of the normal temperature variation. Among these

monkeys which had been under observation there was one which was markedly tuberculous, and its temperature throughout the experiments differed from that of the normal individuals of the same species. Although these experimental animals were very sensitive to changes, the tuberculous monkey responded even more quickly than the others. The effect of alimentation on the temperature was next investigated and the animals were deprived of solid food for seventy-two hours, water alone being allowed during this period of starvation. The temperature fell after the first day, but in the tuberculous monkey, whose temperature at this time was fully a degree higher than the normal, much the most marked fall was noted. The fact that the temperature of all the monkeys fell simultaneously shows that the depression must have been due to the same cause. It is not likely that any change in the diseased conditions could account for a fall so identical in character, occurring in both the normal and the tuberculous. At the close of the period after food was taken the temperature resumed its former high level. This seems to show that gastrointestinal metabolism has a very distinct influence in sustaining a rise of temperature in tuberculosis. The excessive action of gastrointestional metabolism is quite in accord with clinical experiences, although the above observation would tend to emphasize its importance.

Plague Vaccination.

Since plague is fortunately one of the diseases against which a rigid quarantine is entirely protective, there is little in connection with it that will, we hope, ever be of directly practical importance to the American physician. But laxity in quarantine methods has been known to occur, and in any case considerable general interest must be aroused by any advance in the therapy of a malady which has been able to claim a million lives in one year in India alone, and which is a constant and dangerous scourge in many of the countries of Eastern Europe, Asia, and Africa. Such an advance seems to have been made by Dr. R. P. Strong of the Government Bureau of Science at Manila, during the past year. The previous attempts at protective inoculation against this disease have consisted either in the very early and primitive endeavors to produce a mild form of the disease by vaccination with pus from the plague bubo, or, more recently, as the result of the work of Haffkine, Yersin, Lustig, and others, in protective inoculations with dead cultures or bacterial extracts of *Bacillus pestis*. The latter methods have had extensive tests. In Zanzibar during the recent epidemic they were applied to some 20,000 individuals, and in India Haffkine has used his own "prophylactic" upon thousands of people in various districts. Slightly favorable results undoubtedly were obtained, but experiments made by Kolle have shown the method to be, on the whole, disappointing and not at all reliable. The work done by Strong was based directly upon experiments by Kolle and Otto, who in 1904 and 1905, had succeeded in immunizing a number of guinea-pigs by treating them with attenuated cultures of the pest bacillus. This had been previously done by the German and Austrian Plague Commissions, but was abandoned as a practical method because of the great difficulty in producing cultures of a sufficient degree of attenuation. Kolle and Otto weakened their organisms by growing them for a long time upon artificial media at high temperatures (41° to 43° C.), and by adding alcohol to the bouillon used. They succeeded in procuring cultures of *B. pestis* which seemed almost entirely to have lost their pathogenicity, but which nevertheless were able when injected into guinea-pigs to immunize the animals absolutely against later injections of virulent cultures of the same organism. Strong obtained strains of these attenuated cultures from Prof. Kolle, and after carefully determining upon animals their harmlessness, injected extremely small doses into some criminals under sentence of death. The doses were gradually increased without noticeable harm until at the present time forty-two persons in all have been inoculated with large doses of these organisms. Animals treated with the same strains have already proven immune to virulent cultures of *B. pestis*, and it does not seem to be straining analogy to believe that the human beings so treated have been immunized as well. Dr. Strong's precautions appear to have been perfect, and his note of warning in regard to the thorough attenuation of cultures before their use for human immunization proves the utter absence of the element of recklessness in his rather daring experimentation. It appears not unlikely, if his results are confirmed by others, that true vaccination against plague will be a thing of the near future and a boon to many countries.

An Unsatisfactory Medical Term.

There are a number of descriptive terms applied to a variety of diseases which are acknowledged to be unsatisfactory and indefinite, and yet the numerous suggestions made for substitutes have failed of adoption. Among these may be mentioned the word "rheumatism," which is still in constant use to denominate pathological conditions which it entirely fails to describe. Like so many other medical terms, its adoption by the laity has fixed it in our language, but this fact should not interfere with the attempts to find a more suitable scientific appellation descriptive of this systemic disease. It has come to be quite commonly accepted by many medical writers that a toxemia constitutes the basis of all disorders ordinarily classified as "rheumatic." Some believe that this is of exogenous source, others that it is the expression of a disordered metabolism; but very likely it is a combination of both, and until we are more intimately acquainted with the specific nature of the disease general terms must still be employed to describe it. H. A. Fairbairn, writing in the *New York State Journal of Medicine* for March, 1906, suggests that the generic term "toxic" will satisfy both theories, and as the local manifestations are of an inflammatory nature, the ending "itis" may be appended to the part most prominently affected. Thus there results the combination, "toxic arthritis," and although this is also somewhat indefinite, it nevertheless suggests the source of the disturbance, which the other does not. In order to avoid confusion with gout, the writer applies the term "uric-acidæmia" to the latter. Both "malaria" and "rheumatism" have constituted a haven of refuge for obscure complaints without end, which have been admitted to one of these classifications because it was the most convenient thing to do. When a disease condition is without pathognomonic characteristics, we must rely on a certain symptom complex in order to make a diagnosis, and this method has been applied in those states denominated rheumatic. We are unable in the present state of our knowledge to determine the specific agent which causes the condition to which the term rheumatic is ordinarily applied, but it bears most of the earmarks of an infectious process, the result of which we may describe as a toxemia. Fairbairn's suggestion that we refer

to the condition alluded to as a toxic arthritis, seems quite logical, and it might well be adopted until a more intimate knowledge of the etiology will afford the means of furnishing us with a more appropriate appellation.

Restriction in the Use of the *X*-Rays.

It is quite generally admitted that in the *x*-ray we have a very powerful therapeutic agent which is of undoubted value in inoperable malignant disease of a superficial character and also as a preventive against recurrences of the same after operation. But the field of application of this procedure has been gradually extended by its enthusiastic advocates to a varied assortment of pathological conditions, and among these we find very prominently noted certain affections of the lymphatic and glandular systems. Notwithstanding the many favorable reports which have been circulated regarding the effects, there are numerous uncertainties connected with the employment of the *x*-rays in this class of cases. If the expected result does not materialize, resort must finally be had to surgery, and in many of these cases, on account of the alterations produced in the tissues by exposure to the rays, operations which would ordinarily be simple and easy dissections become formidable and dangerous. W. J. Taylor, in an article in the *Annals of Surgery* for March, 1906, calls attention to this matter and illustrates by practical example how the change in the character both of the skin and of the underlying tissues may interfere with the otherwise favorable outcome of surgical operations. The alterations referred to are particularly well marked in cases of enlarged cervical glands, especially those of the tuberculous variety. Ordinarily these glands are comparatively easy to enucleate and the neighboring blood-vessels and nerves retain their distinct characteristics, but after treatment with the *x*-rays has been employed, the glands are hardened and perhaps shrunken, and while it is true that in cases of recent origin many of the swollen glands may disappear, this is not usual. In addition to the changes in the glands themselves, the surrounding structures, blood-vessels, nerves, etc., are so altered that they can be distinguished only with difficulty and the danger, the difficulty, and the time consumed in the operation are thus materially increased. This report is in line with others of a similar nature regarding the disadvantages connected with the use of the Röntgen rays as a therapeutic agent in cases in which it is not distinctly indicated.

News of the Week.

Children's Seaside Hospital.—The Association for Improving the Condition of the Poor has received contributions completing the sum of $125,000 necessary in order to secure Mr. John D. Rockefeller's promised gift of an equal amount for the erection of a seaside hospital devoted to the treatment of tuberculous children. The time limit had almost expired and $19,850 were still lacking when an anonymous contributor pledged himself to make good the deficiency. Now that the money for the hospital has been raised the city is to be asked to provide the site, and the Acting Mayor has promised to bring the matter before the Board of Estimate.

A Tuberculosis Sanatorium for Yonkers.—A tract of land in the Seventh Ward, comprising 110 acres, has been purchased by Mr. Alexander Smith Cochran, who will erect on it a sanatorium for consumptives and present it to the city of Yonkers. The estimated total cost is $500,000, and an endowment sufficient to pay all expenses for the first five years is promised. The treatment will be free to the patients, and incipient cases will have the preference. It is expected that the hospital will be opened late in the fall.

For the Physical Welfare of School Children.—Announcement is made of the organization of the New York Committee on the Physical Welfare of School Children. The formation of this body is the direct outcome of the very large number of appeals made last year by the principals of schools to the Association for Improving the Condition of the Poor in order to secure for children clothes, shoes, eyeglasses, better nourishment, etc. It is not expected that the committee will itself provide material relief or fresh-air outings for needy children. It is believed, however, that there are private and public agencies in existence that will effectively cooperate with health and educational authorities to secure prompt attention for children whose physical condition is below normal, and the committee will assist in the distribution of assistance.

Panic in New York Public Schools.—Owing to a report made by the school authorities that a number of children in one of the East Side schools required removal of adenoids and tonsils, and that their parents were too poor to pay carfare to go to a dispensary where they would be treated, several hospital physicians offered to go to the school and operate upon those children whose parents consented in writing thereto. Consequently three specialists, assisted by seven inspectors of the Health Department and as many nurses, operated on eighty-three children on June 21. Six days later a large number of parents, believing that the children in all the schools were to be operated upon, or, as the rumor had it, murdered, rushed to the schools, demanded their children, and, becoming excited, demolished windows and doors before the pupils could be dismissed. This occurred in the districts east and south of Houston street, where the Russian and Polish immigrants live. The next day the Italian district was the scene of a similar excitement. There was no intention of visiting other schools, but in this particular school the children who were operated upon were the ones selected by the Society for Improving the Condition of the Poor to be sent to the country, and it was the opinion of those interested that the fresh air benefit would be enhanced if the operations were performed first.

Cholera in the Philippines.—A dispatch from Manila reports that cholera has reappeared in that city and the surrounding provinces. Four Americans in Manila had been stricken up to July 3, and one had died. Twenty-one cases and sixteen deaths were reported on that date in Manila, and in the provinces there were twenty-six cases and twenty-five deaths.

The President of the Chicago Union Hospital has asked the Circuit Court to restrain the Building Commissioner and the Chief of Police from interfering with the erection of a new hospital building at Wellington avenue and Dayton street. Work on the building has been ordered stopped by the Commissioner of Buildings, for the reason that the building is being erected in violation of a city ordinance which forbids a hospital within four hundred feet of property used for public school purposes.

Dr. Darlington Injured.—Dr. Thomas Darlington, Health Commissioner of New York City, was severely hurt in a runaway accident on June 30,

while on a tour of inspection of the city's new tuberculosis sanatorium at Otisville, N. Y. While his injuries are severe, they are thought not to be dangerous.

The "Canadian Journal of Medicine and Surgery" devotes the greater portion of its July number to matter relative to the meeting of the British Medical Association, which is to be held in Toronto in August. The issue contains many photographs of men prominent in the Association and of Toronto's public buildings, and is replete with information of value to all who may be interested in the British Medical Association and its approaching meeting—the second, we believe, which has been held in the Western Hemisphere.

A New Gastrointestinal Clinic.—The Brooklyn Central Dispensary, 29 Third avenue, has created a Department of Gastrointestinal Diseases, which will be under the supervision and direction of Dr. Mark I. Knapp of New York. Clinical lectures on gastrointestinal cases will be held by Dr. Knapp every Wednesday afternoon at 3 o'clock, to which all physicians are welcome. Regular postgraduate courses in gastrointestinal diseases will be given at the dispensary, commencing in the fall of this year.

Philadelphia Slaughter Houses Condemned.—The Philadelphia Bureau of Health on June 26 condemned thirty-seven of the one hundred and seventy-one slaughter houses in the city, on account of unsanitary conditions.

A Hospital for Bronxville.—Mr. W. V. Lawrence has purchased a tract of land in Bronxville, comprising about two and one-half acres, and has signified his intention of erecting on it a hospital and presenting the same to the town Bronxville.

"Using" the Illinois State Board of Health.—Dr. James Egan, Secretary of the Illinois State Board of Health, has issued a statement correcting certain assertions made in regard to the cure of an alleged advanced case of tuberculosis by some specific remedy. Wide publicity was given to the assertion that the patient's sputum had been examined by Dr. Egan and that he had stated that the patient was suffering from advanced tuberculosis. Dr. Egan says that since the publication of this story the State Board of Health has been flooded with inquiries in regard to the remedy, whereas the only connection of the board with the case is that the patient's sputum was examined at the official laboratory at the request of a physician, and that it was found to contain a few tubercle bacilli. No opinion was expressed as to the stage of the disease, and, owing to the way in which the facts of the case have been distorted, it is suggested that the whole matter is merely an advertising dodge to exploit some new "consumption cure."

New Medical Society.—The Medical Society of the Twenty-sixth Recording District of Indian Territory was organized at Marietta on June 17 by Dr. H. P. Wilson, Councilor for the Oklahoma State Medical Association. The following officers were elected: *President,* Dr. A. E. Martin; *Vice-President,* Dr. B. S. Gardner; *Secretary and Treasurer,* Dr. J. D. Batson.

Lake Keuka Medical and Surgical Association.—The seventh annual meeting of this society was held this week at Grove Springs, Lake Keuka, under the presidency of Dr. W. B. Jones of Rochester, N. Y. The secretary for this meeting was Dr. H. B. Nichols of Poulteney, N. Y.

West Virginia State Medical Society.—At the annual meeting of this society, held on June 22 at Webster Springs, the following officers were elected: *President,* Dr. W. W. Golden of Elkins; *Secretary,* Dr. E. W. Moore of Huntington. The next meeting will be held at Huntington.

American International Congress of Tuberculosis.—The officers of this congress announce its next session for November 14, 15, and 16, 1906, in this city. The president is Dr. F. E. Daniel of Austin, Tex., and the secretary is Dr. M. M. Smith of the same city.

Mississippi Medical College. — This institution will open the session of 1906-1907 in October in its new building now in course of erection. The officers elected are as follows: *President,* Dr. W. W. Hamilton; *Vice-President,* Dr. T. A. Barber; *Secretary,* Mr. O. W. Bethea; *Treasurer,* Dr. T. J. Houston; *Dean,* Dr. N. L. Clarke.

Chicago Clinical School.—The annual meeting of this school was recently held, and the following officers were elected: *President,* Dr. W. T. Eckley; *Vice-President,* Dr. George F. Hawley; *Secretary,* Dr. Arthur M. Corwin; *Treasurer,* Dr. John S. Nagel.

Death of Manuel Garcia.—Manuel Garcia, celebrated as an operatic tenor, as a teacher of singing, and especially as the inventor of the laryngoscope, died on July 1, at his home in London, in his 102d year. The achievements of this remarkable man were brought prominently forward on the occasion of his centenary, celebrated on March 17, 1905. Born in Madrid of a family unusually gifted in vocal music, he was educated as a professional singer, but in 1829 he gave up the stage and began to devote himself entirely to teaching. His ability soon won recognition, and in 1835 he was appointed Professor of Singing at the Paris Conservatoire. In 1840 he presented his "Memoire sur la Voix Humaine" before the French Academy, which, as well as his "Traité Complet de l'Art du Chant," published seven years later, gained for him a world-wide reputation. The manner in which an inspiration coming suddenly to him in 1854 led to the development of the laryngoscope may be found, described in his own words, in an article by Dr. James E. Newcomb, appearing in the MEDICAL RECORD March 25, 1905. He preserved almost until the last a degree of mental and physical vitality characterized as nothing short of marvelous, and his later years were passed in peaceful enjoyment of the distinction which his achievements had secured for him.

Obituary Notes.—Dr. W. G. ALBAN of Walla Walla, Wash., one of the oldest physicians in the State, died on June 20, at the age of eighty-five years. He went to California in 1849 and removed to Washington in 1878. He continued in active practice until two years ago, serving twelve years as city health officer.

Dr. L. Y. GREEN of Chattanooga, Tenn., died on June 21, at the age of seventy-seven years, after a long illness. He was born at Perryville, Ky., and began the practice of medicine in Mississippi in 1851. He removed to Chattanooga four years later and served in the Confederate army as a surgeon. Declining health compelled him to give up active work three years ago.

Dr. H. C. WILLISON of Port Townsend, Wash., died on June 12, at the age of sixty-one years. He was born in Indiana and was a graduate of the Michigan State University, at Ann Arbor, and the Bellevue Medical School, at New York. In 1875 he went to Port Townsend, which has been his home ever

since. Dr. Willison was for several terms President of the Washington State Medical Association and served for a number of years as a member of the State Board of Medical Examiners.

Dr. J. I. Boone of Chickasha, Ill., died on June 10, at the age of thirty-five years. He was graduated from the Missouri University Medical School at Kansas City in 1903.

Dr. John H. Henry of Montgomery, Ala., died on June 19, at the age of seventy-seven years. He was born in Montgomery and was graduated in 1850 from the Philadelphia College of Homeopathy.

Dr. Arthur G. Cabell, a retired surgeon of the United States Navy, died on June 19, in Richmond, Va., at the age of fifty-two years. He was born in Richmond and was graduated from the Medical College of Virginia, entering the naval service immediately afterward.

Dr. T. E. Sanger of Littleton, N. H., died on June 6, in Boston, at the age of seventy-four years. He was born at Troy, Vt., and in 1856 was graduated from the Philadelphia College of Homeopathy. He first located at Hardwick, Vt., and in 1858 removed to Littleton. He was the first President of the Connecticut River Valley Homeopathic Medical Society.

Dr. Thomas J. Yarrow, son of the late Dr. Thomas J. Yarrow, of Philadelphia, died at Cape May, N. J., on June —, at the age of forty years. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1894.

Dr. Jeremiah W. Rowe died at Altoona, Pa., on June 30. He was graduated from Jefferson Medical College in the class of 1871.

Correspondence.

APPENDICITIS *VERSUS* COLITIS.

To the Editor of the Medical Record:

Sir:—In my opinion, Dr. Dieulafoy has lately brought before the Academy of Medicine of Paris a subject of great importance, relative to the diagnosis and treatment of so-called appendicitis. He has shown that in many instances French surgeons have operated where there was no appendicitis, but the symptoms properly understood, before and after operation, pointed undoubtedly to typheocolitis as being the disease present. The appendix in these cases was shown to be normal, and in those instances where strictures and thickening were present they were probably caused by or connected with a preceding attack, or attacks, of colitis. Dieulafoy limits the errors accused to cases of mistaken differential diagnosis of "mucous colitis" and appendicitis. In my judgment his appreciation should be broader. Ordinary cases of colitis of the catarrhal variety probably are often confounded with appendicitis, and operated on as such. The differential diagnosis has not been made with sufficient care, and error has arisen mainly because the so-called McBurney's point may exist, and does exist, quite frequently with simple colitis, and because the irregularities of the bowels seem to be explained by the presence of appendicitis, when in reality they are caused by colitis.

The appendix is removed and examined almost invariably —macroscopically and also microscopically—by careful men. The disregarded cecum is not, cannot be, examined, and consequently is to-day ruled out as practically non-existent. There is no doubt in my own mind that formerly, as we know, the cecum was made much of—too much—and the appendix ignored. To-day we see just the reverse of the medal all the way along the line. Happily someone arises finally who sees and talks straight, and this one may be and now is such a commanding personality that he challenges inquiry which must be listened to and regarded with closest, most earnest attention. Many great surgeons of France oppose his views, and yet they respect and honor them, because he rings true. He, Dieulafoy, as the writer, has always desired and endorsed sane and wholesome surgery; what he is opposed to always, and unalterably, is surgery that he feels will ultimately be obliged to retrace its steps and grant the medical man the hearing and consideration which proceed from the larger view of the physical organism of man, and which recognizes inactivity at times as "masterly" and the greatest human wisdom, when all sides of a question are calmly and rationally considered and duly weighed in the balance. I have written what precedes, filled with the importance of it, and corroborating and re-echoing only what Dieulafoy has so forcibly and truly, as I believe, defended and sustained.

Beverley Robinson, M.D.

42 West Thirty-Seventh Street, New York.

AMERICAN BORN BUT OF FOREIGN ADOPTION.

To the Editor of the Medical Record:

Sir:—In your issue of June 23, Dr. Hartzell writes as follows: "In 1896 Darier prepared the term *tuberculide* for a series of dermatoses, the individual members of which had been described from time to time under a variety of names. This name was at once adopted by the French, and has been slowly taken up by writers in England and Germany, and, to a less extent, in America."

That it has been "slowly taken up in America" is possibly due to the fact that the name really originated here. Some writers appear to prefer to quote from or refer to European authors, rather than to their American colleagues. In a paper read by the undersigned before the New York Academy of Medicine, April 2, 1891, as published in the Transactions of that body, will be found the following sentence: "If we now accept the prevailing doctrine, that certain cutaneous affections are the result of infection by the tubercle bacillus, it may be convenient to group them under the common title of *tuberculides*," etc.

The coolness with which the French adopt American ideas and rechristen them may be exemplified by the following instances: (1) The *undulatory* galvanic current described by me in the *New York Medical Journal*, July 11, 1891, reappears in the *Revue internationale d'Électrothérapie*, 1899, p. 318, as the discovery of d'Arsonval and Apostoli. (2) In the Medical Record of July 21, 1877, I strongly advised curettage *followed by the actual cautery* in the treatment of lupus. Some years later this method was signalized in France as "Brocq's treatment."

H. G. Piffard, M.D.

256 West Fifty-seventh Street, New York.

OUR LONDON LETTER.

(From Our Special Correspondent.)

THE KING'S SANATORIUM—FOOD INSPECTION—METCHNIKOFF ON SYPHILIS—INFANT MORTALITY—UNIVERSITY AND COLLEGES—TROPICAL SCHOOL—HOSPITALS—COLLEGE OF SURGEONS —THE LATE SIR HALLIDAY MACARTNEY, M.D.

London, June 15, 1906.

King Edward VII. Sanatorium, respecting which I have kept you informed, was opened on Wednesday by His Majesty, who was accompanied by the Queen. It was a great day for the little town of Midhurst, and all along the three and a half miles from there to the sanatorium their majesties were cheered by the enthusiastic people who had come to see them, while arches, festoons, and flags made all the route gay. You will remember that when Sir Ernest Cassel offered the King £200,000 for philanthropic work His Majesty determined to devote this munificent donation to a sanatorium which should be as perfect as possible and thoroughly equipped for research. The site selected is admirably adapted for the purpose, about 150 acres in extent. The building is on the southern slope of a hill 494 feet above sea level, and the ground behind rises to 630 feet. The intention is not to provide for the very poor, but rather for the professional classes who fall victims to phthisis and are not able to afford the expense of treatment in private sanatoria.

But His Majesty desired that wealthier persons should not be absolutely excluded, and accordingly twelve rooms are set apart for them at a rate of 8 guineas per week, the other eighty-eight rooms being for those who can afford 2 guineas a week. Isolated from the other buildings is the pathological laboratory. Clinical and research laboratories are also provided, where it is intended that scientific work, both preventive and curative, shall be one of the prominent objects of the institution.

In the course of an interesting speech on the occasion the King said it gave him and the Queen much pleasure to be present, that it had always been their endeavor to do all within their power to mitigate suffering and to check the ravages of disease. He referred to the Queen's interest in the fight against tuberculosis as having become the patron of the institution at Davos, and then added: "It is our earnest wish that the sanatorium now opened and its research laboratories, equipped with every resource of modern science, may assist to advance the physiological knowledge of pulmonary diseases, and that this institution may, by

treating the disease in its early stages, be the means of prolonging the lives of those whose career of honorable usefulness has been interrupted by this terrible malady. I pray that God's blessing may rest upon this building and upon all who work within it, and all who come to it for aid, and that it may be a means of alleviating suffering and saving life for this and many generations to come."

Their Majesties then went for a long tour of inspection over the buildings, accompanied by members of the advisory committee, and at the conclusion expressed their great pleasure at all they saw.

The public is just now greatly exercised on one sanitary matter—its food supplies. Tinned meat is tabooed, and the press is demanding whether our home products can be as disgusting as importations. There is a reform regarding the matter, that medical men have demanded for years, that may possibly be now obtained, viz., security of tenure for medical officers of health and inspectors. At present in many country districts these officials are elected from year to year, and it is easy for an unscrupulous district councillor who has had an unfavorable report made about him to oppose the reelection of the officer who has done his duty. There seems no reason why the London law should not be extended throughout the Kingdom. The qualification of inspectors is also beginning to receive more attention. The Royal Sanitary Institute established examinations several years ago which have been approved by the Local Government Boards of England, Scotland, and Ireland. These examinations are held in the chief centers and are very practical, specimens of meat, fish, tinned and other preserved foods being submitted to candidates. Nearly 200 certificates of competency have been issued, and a good proportion are held by those having appointments in the principal towns or ports. But if the public is to be assured and inspection to be efficient, it will be necessary for a qualification of the kind to be made compulsory on all inspectors. The Chicago revelations have been discussed in the House of Commons, and the War Minister has sent a lieutenant-colonel to inspect and report. Challenged as to why he did not rather send a qualified medical officer, he maintained that an officer of the Army Service Corps had sufficient knowledge of sanitation. His action gives dissatisfaction, and people say it is a new lesson in "how not to do it."

Professor Metchnikoff devoted his concluding Harben lecture to hygienic measures against syphilis. Some of his ideas and statements seem to have excited considerable surprise, but the facts he related are very interesting. He called attention to the prevalence of nonvenereal syphilis where hygiene is altogether neglected; *e.g.* in some of the rural populations of Russia ignorance, poverty, and promiscuity disseminate the disease among little children by means of their games and caresses. Admitting that it is not by itself a fatal disease, he said malignant cases led to septicemia and others tended to shorten life by bringing about mortal diseases, and that next to tuberculosis syphilis exercised the more important rôle on the death-rate of insured persons, that is, the most vigorous part of the population. He referred to the subject of regulation of prostitution, to the proposal of some to instruct young persons as to the dangers of infection, and of others to promote early marriages. The objections to such means of prevention were mentioned, but indeed they have not abolished disease. The suggestion of vaccines must wait, he said, until cultures of the organism could be had. But he related recent experiments showing that the virus may be attenuated by passage through different animals. An accidental inoculation of an assistant in his laboratory who often handled infected monkeys is instructive. One day he noticed an ulcer on his lower lip which seemed suspicious, but the glands were not affected. It healed and was forgotten until a month later, when a similar lesion on the same lip induced him to ask advice. The glands were still unaffected, but to be quite sure a Javanese macacus was inoculated from the small ulcer, and, to the surprise of those concerned, four weeks later two typical primary lesions appeared on the macacus, and these lesions teemed with Schaudinn's spirilla. Fournier was consulted by the assistant and found nothing to justify a diagnosis of syphilis or to require mercurial treatment. No symptoms occurred for six months, which supported Fournier's opinion. Thus this assistant did not suffer from syphilis, but the ulcer on his lip caused a primary lesion on the monkey. This contradictory result the lecturer explained by assuming that the man was accidentally inoculated with a virus which acted as a very attenuated one.

Of course the professor satisfied himself that he might exclude the hypothesis of a former syphilis. Then he consented to the inoculation of a human being with virus passed through a macacus. Twelve days after there appeared two small nonulcerated pustules of a reddish brown just like those of secondary syphilis, which after disappearance left two pigmented spots. No glandular or other affection followed for six months. From these facts it was said the macaci may attenuate the syphilitic virus both for themselves and for man. Still, the professor said, they were but a first indication, and we are far from possessing an antisyphilitic vaccine, while, even if later the existence of one could be proved, it could be used only under very exceptional conditions. In fact, it might cause serious complications, for it is known that general paralysis and tabes occur in patients with quite insignificant signs of syphilis. But the lecturer seemed to think that further researches may make it possible to resort to such a measure of prevention in some cases, and he instanced children exposed to infection from relatives. But so many difficulties would beset this plan that other means of prevention deserve attention, and Professor Metchnikoff mentioned the suggestion of Cohn and Guiard as to mercury, and added that from a long series of experiments with mercurial preparations applied after inoculation of monkeys he concluded that such methods were valuable. He had afterward inoculated at his own request a medical student from chancres of two men. An hour afterward, the parts inoculated were rubbed for five minutes with calomel ointment, 1 in 3. Nothing followed. Four macaci were similarly treated as controls. Two showed lesions seventeen days later. The third was treated with calomel in an hour and remained free. The fourth, treated twenty hours after, had a primary lesion on the thirty-ninth day. That experiment showed that prophylaxis was attainable. Professor Metchnikoff did not pretend to discuss the morality of people who acquired syphilis through illicit sexual intercourse, but he suggested that many victims are absolutely innocent and should be protected. Those who regard prophylactic measures as immoral, he said, should apply the same arguments against antiseptics in midwifery, because they facilitated criminal abortion, and, to carry the argument to the end, they should oppose treatment as well as prophylaxis. True morality, he held, should promote prevention of all diseases, should not try to lead, but should rather follow, hygiene.

Mr. Burns, President of the Local Government Board, spoke at the National Conference on Infantile Mortality and said his department would render all the practical help it could. He might bring in a small bill to legalize municipal milk depots. Drinking among women he put as one of the serious tragedies confronting society. If he had his way married women should not be allowed to work in factories for three months before or six months after lying-in. "To reduce infant mortality they must concentrate on the mothers: let them glorify, purify, and dignify motherhood." Dr. Sykes reinforced this and added that the mothers should be urged to suckle their infants, for no strong race could be reared on the bottle. At the adjourned meeting yesterday resolutions were passed in favor of earlier registration of all births, and, as to still-births, that a medical certificate be required for burial. In regard to insurance, about which much has been said, Dr. Fraser said that a few years ago he instituted inquiries at Portsmouth and obtained irrefragable proof that there was no foundation for the sweeping statements that had been made as to children being insured by unscrupulous parents for the sake of the money insured for. Child insurance as regards causing infant mortality he declared to be an absolutely negligible quantity. A resolution was passed that steps ought to be taken to supervise the persons and places where infants are received for day nursing.

Sir Donald Currie on Monday laid the foundation stone of the new buildings he is presenting to University College Hospital. They comprise a School of Advanced Medical Studies, a Maternity Students' House, and a Nurses' Home. They cover an area of 18,290 square feet. Sir Donald expressed pleasure at the progress made with the work and his confidence in the future usefulness of the hospital.

Sir A. W. Rücker delivered the "Foundation Oration" at University College on Wednesday, in which he spoke of the extraordinary novelty of a number of distinguished gentlemen banding themselves together to establish what was intended to be a London University—undenominational—at a time when the only two universities in England were strictly denominational. He found one in every twenty-two students of the college were from the colonies, showing it had done its work, not only for London, but for the Empire. The approaching incorporation with the university would in no way injure the college, and he believed Kings College also would follow suit. This would lead to the confederation of London colleges with the university.

Your papers are probably circulating telegrams from Paris, such as ours are receiving, to the effect that Drs. Calmette and Guérin from many experiments on animals with tubercle bacilli conclude that they can be rendered immune by taking by the stomach bacilli which have been treated by heat. They even suggest that infants might be rendered refractory to tuberculosis by a dose of the properly

prepared bacilli given a few days after birth, followed by a second dose a few weeks later. Drs. Roux and Vallée are said to have been working on the same lines and obtained similar results.

The Hon. Bomanjee Dinshaw Petit, the munificent Bombay merchant who did much towards founding the London School of Tropical Medicine, went over it on Monday with the teaching staff and was entertained at luncheon. He expressed confidence that India would give substantial assistance toward its investigations concerning plague.

H. R. H. the Duchess of Albany opened a bazaar and floral fête yesterday on behalf of the Waterloo Hospital for Women and Children. The reception of nurses was an interesting ceremony, many being brought by infants in arms. The first, in fact, was conveyed by the infant of Prince and Princess Alexander of Teck and contained a gift of Mr. J. S. Watts, who sent with them 120 guineas. Altogether £700 was given in purses; and it is expected the bazaar will realize £2,000. The Lady Mayoress is to open it this afternoon. Mrs. Longworth and Mrs. Whitelaw Reid are to be at the American stall.

Yesterday at a meeting of the Governors of St. Mary's Hospital it was stated that the Clarence wing, although finished and capable of accommodating sixty beds, remains empty for want of funds to furnish. The cost per bed last year was £88-13-2, comparing favorably with £100-13-2 in 1904. The reduction cannot be expected to continue at the same rate. As to the new wing, it looks as if the managers had been in too great a hurry to indulge in building. Hospital managers seem always to be reckless in so far as not counting their cost beforehand.

The Council of the Royal College of Surgeons yesterday received the report of the committee appointed to consider the question of admitting women to the examinations. The committee recommended that the fellows and members be consulted as to the desirability of approaching the Royal College of Physicians on the subject, and the Council adopted the recommendation.

Sir Halliday Macartney, M.D., late Counsellor and English Secretary to the Chinese Legation in London, died rather suddenly on the 8th inst. He retired about six months ago, after a long and distinguished career. When a student he joined a contingent of volunteers for service in the Crimea. At the close of that war he returned to Edinburgh and graduated M.D. He then entered the Army Medical Service and went to India and China. After the peace he took service in China, being given military rank and command. He established an arsenal at Nankin and was governor of it for twelve years. In 1876 he was sent to England on a special mission. Later China established a permanent mission, of which he was appointed European Secretary. He was intimately acquainted with Chinese customs and did much to promote accurate notions of Western ideas in the East. He received the C.M.G. in 1881 and the K.C.M.G. in 1885. He negotiated the Burmah treaty in 1904, the Opium convention (1885), and that relating to the Chinese in the Transvaal, 1904.

OUR PARIS LETTER.

(From Our Special Correspondent.)

PROPHYLAXIS OF SYPHILIS—MILITARY SANITATION—ESOPHAGOTOMY FOR A FOREIGN BODY—A NEW SIGN OF PYOPNEUMOTHORAX—THE REPRESSION OF QUACKS—FOURTH COLONIAL CONGRESS.

PARIS, June 23, 1906.

AN interesting communication was presented before the French Academie de Médécine by Metchnikoff and Roux of the Pasteur Institute on the prophylaxis and cure of syphilis. After reviewing the observations they had already made on the transmission of syphilis to the monkey the authors reported the results of new experiments undertaken to demonstrate that inoculation with syphilitic virus can be made harmless to man if certain preliminary measures are taken. Before making the experiment the authors carried out a series of tests on monkeys which demonstrated conclusively that the application of a 30 per cent. ointment of calomel made at the point of inoculation several hours later prevents the development of all syphilitic lesions. After having obtained this same result in thirteen cases the authors then repeated the experiment on man. A medical student free from hereditary or acquired syphilis volunteered to serve as test object. On the first of last February the inoculation was made in the preputial sulcus with virus from two hard chancres, one of which had existed eight days and the other one month. Five monkeys were inoculated with the same virus, but one of these died of bronchopneumonia several days later. One hour after the inoculation the calomel ointment was during eight minutes massaged into the inoculation wound of the student and one of the monkeys. The same thing was done twenty hours later to a second monkey, and the two others were kept as controls. The initial lesion appeared in these seventeen days later, and in the case of the monkey treated after twenty hours on the thirty-second day. On the other hand, no evidences of disease appeared in the student either in the skin, the mucous membrane, or the glands, and the same thing was true for the monkey that had been similarly treated. Three months have passed since the experiment, and it therefore seems that in future it will be possible to use calomel ointment as a prophylactic against syphilis.

Hallopeau stated that he had taken up these observations with Neisser, who, after having repeated the experiments on monkeys, admitted their correctness. Hallopeau asked whether the use of such concentrated ointments did not give rise to manifestations of irritation. Metchnikoff replied that the present experiment on man was insufficient in some respects, but was of great interest, since it was in entire conformity with experimental results. The calomel ointment did not cause any irritation.

Lemoine and Simorin read before the Académie a paper on sanitary conditions in the army in which the barracks of the soldiers were discussed. The authors had investigated one hundred and thirty-four barracks in which a total of 95,000 men were lodged. It appeared that the mode of construction of the barracks was not of the greatest importance for the health of the troops. The dissemination of contagious diseases in the regiments was rather dependent on the size of the garrison, and also on the sanitary condition of the cities in which the barracks were situated. Accordingly it was found that in old barracks sheltering only four or five hundred men infectious diseases were less common than in new buildings containing from nine hundred to a thousand soldiers. The character of the buildings did not seem to play any rôle in the origin and spread of typhoid fever. Though pulmonary tuberculosis is more often observed in old barracks, this is because the latter are usually situated in large cities where the life of the soldier is much more strenuous, so that here again the buildings cannot be incriminated. The conclusion is that the military authorities should attempt to put smaller numbers in each dormitory, and preferably to construct small buildings for reduced numbers, and to insist on improvement of the sanitary conditions in the cities.

Richelot reported before the Société de Chirurgie a case of external esophagotomy for a foreign body followed by death. The patient was a man of sixty-five years who had swallowed his false teeth while asleep. After several vain attempts had been made to remove the foreign body Richelot was called the second day after the accident. Further attempts with esophageal instruments were unsuccessful, and on the fourth day external esophagotomy was performed with a temporary gastrostomy for purposes of feeding. The patient died forty-eight hours later of pneumonia. This report gave rise to a long discussion in which Sébileau, Pozzi, Picqué, Tuffier, Kirmisson, Delbet, and Quénu took part. All of these surgeons were unanimous in stating that foreign bodies in the esophagus, when irregular in shape, like false teeth, demand immediate esophagotomy, whereas the removal of smooth elastic bodies, pieces of money, buttons, etc., should be attempted without this measure. They also recommended suture of the esophagus after esophagotomy, which was not done by Richelot on the ground that it is not likely to hold. It was stated that on the contrary it was not unusual to obtain healing by first intention, and that even when the suture held only partially the resulting sinus closed much more rapidly than when the esophageal wound was left open. Mauclaire closed the discussion by recalling a case in which he removed by esophagotomy false teeth which had remained in the tube twenty-three days; recovery followed without complications. He stated that in such cases esophagotomy should never be done without making an attempt to remove the object with the aid of the esophagoscope.

A new sign of pyopneumothorax was described by Chauffard before the Société Médicale des Hôpitaux. In cases of pneumothorax in which the fluid is in great excess it is known that Hippocratic succussion as ordinarily practised is negative. The speaker had found in three cases that although succussion was negative while the patient was seated or standing, the phenomenon could be elicited in the recumbent position, or even

when standing with the body very much bent forward. This observation may be explained as follows: To obtain succussion it is necessary for a layer of air to exist over a layer of fluid, and if there is little liquid and much air the conditions are most favorable; if, on the other hand, the volume of air is too small the fluid waves cannot produce sufficient resonance and no succussion is obtained. With the patient in the horizontal position the relation of the two layers is changed, and owing to the greater area of the layer of air succussion is produced. This was illustrated by showing two bottles, one half filled with water and the other filled well into the neck. With the first succussion could be obtained in any position, but with the second the sound was produced only with the bottle in the horizontal position.

For the first time a congress is being held in Paris for the repression of the illegal practice of medicine, with the object of securing suitable legislation. The members of the legal profession are aiding the physicians and are assisting in the effort to exterminate the horde of quacks, charlatans, magnetic healers, etc., which is continually increasing in numbers and under the present inadequate legislation has become a menace to the body medical. The congress was held May 28 to 31 under the presidency of Professor Brouardel.

On June 18 the Fourth French Colonial Congress will be opened at Paris with numerous departments on important medical subjects.

OUR VIENNA LETTER.

(From Our Special Correspondent.)

TETANUS—HOURGLASS STOMACH—PRIMARY TUBERCULOSIS OF THE NOSE—PUERPERAL SEPSIS—DISTENTION OF THE CECUM—EXTENSIVE INTESTINAL RESECTION.

VIENNA, June 18, 1906.

THE subject of tetanus was discussed before the Society for Internal Medicine by Professor von Frankl-Hochwart, whose experience in this field has been unusually great. His dissertation was based on the histories of no less than one hundred and sixty cases, fifty-five of which were discussed in some detail. One-fifth of the patients died as a result of the disease, the fatal termination for the most part being due to pulmonary involvement, from which observation the conclusion may be drawn that tetanus is to be regarded more as an intermediate cause of death, since it appears to reduce the powers of resistance against other infections, especially those of the lung. The course of the disease varies greatly in different cases, and the symptoms may subside entirely or may go on to a condition of chronic invalidism. The location and the type of the convulsions are also very irregular; the hands are principally affected, the legs less often, though the abdominal muscles, and even those of the eye, may also be involved. Some patients complain of peculiar spasms in yawning; sometimes a peculiar twitching appears in other parts of the body associated with nervousness, mental hebetude, disorders of vision, loss of memory, etc. One patient suffered from spasm only in taking objects in his hand; another only on crossing his legs. Enlargement of the thyroid gland is a frequent condition in tetanus which may be of considerable importance, and the fact that it was absent in the cases in which recovery took place suggests the possibility that when present it renders recovery more difficult. Every case of tetanus is serious, since even after complete disappearance of the symptoms there is danger of relapses. In one case tetanus recurred ten years after the original attack. Even after the characteristic manifestations of the disease have subsided a state of chronic weakness persists, comprising trembling of the extremities, general nervousness, brittleness of the nails, and falling of the hair. The evidence so far seem to show that few people ever recover completely from tetanus.

Blazs operated on a remarkable case of hourglass stomach due to cicatrization of an ulcer. The patient was a woman of forty years who was much emaciated and very anemic on coming under observation. Conspicuous features were the retraction of the epigastrium and the prominence of the meso- and hypogastrium, while a transverse sausage-shaped tumor was palpable above the umbilicus. Colicky pains and vomiting were observed after meals. At the operation it was found that the stomach was divided into two parts in its middle third by a scar running from the greater curvature to the lesser. Gastroenterostomy was performed, as the excision of the cicatricial band was impossible, owing to the dense inflammatory adhesions between the stomach and the head of the pancreas. Since the operation the pain and vomiting have disappeared, the patient takes a mixed diet, and has gained weight.

A case of primary tuberculosis of the nasal mucosa was presented before the Society of Internal Medicine by Panzar. The boy had suffered from nasal obstruction for some months, and on the right side of the cartilaginous septum there was a lesion the size of a ten-cent piece with necroitic surface covered with mucopurulent secretion. The edges of the ulcer were surrounded with small yellow nodules. The infection of the mucous membrane probably followed picking the nose with a dirty finger. The prognosis of tuberculosis of the nose is rather favorable. The treatment consists in curetting and cauterization, and in the case in question injections of tuberculin are also to be tried.

Vertes of Buda Pesth has reported the cure of a case of puerperal fever by extirpation of the uterus. The patient was a woman of forty years who had a difficult still-birth complicated bya large myoma of the cervix. On the third day of the puerperium chills, fever, and offensive lochia were noted. The diagnosis of purulent endometritis was made, secondary to the myomatous condition, but this was soon changed to that of septic infection. As the process was still at its beginning and as a uterine operation would have been necessary later in any case, the author decided to obviate further intoxication by removing the uterus. A panhysterectomy was accordingly done and a Mikulicz tampon was introduced into the peritoneal cavity from the vagina. Staphylcocci in pure culture were found in the uterine veins and in the parametrium. The patient recovered.

Silbermark, together with Ghon, has made experiments on cadavers in order to determine why the cecum should be the favorite seat of overdistention following acute or chronic strictures of the colon. They conclude that this is due to the fact that the peritoneal covering of the cecum permits greater mobility to this portion of the intestine. On this account the cecum is least able to withstand increased internal pressure. Silbermark also found that the anterior and posterior teniæ are the sites of predilection for diastasis of the cecal serosa and ascribes this fact to the lessened elasticity of this portion of the intestinal wall.

Lorenz performed a successful intestinal resection on a woman of fifty-five years from whom half of the small intestine and a considerable portion of the colon were removed for new growth. A primary carcinoma of the cecum had led to the formation of a large sharply circumscribed metastatic tumor of the lymph nodes. This was firmly adherent to the primary growth, and had also become fixed to the freeborder of the omentum and anterior abdominal wall. Several loops of small intestine were also adherent to the mass. It was therefore necessary to resect the portion of the colon involved in the primary growth, the ascending colon, and the hepatic flexure, as well as a section of the small intestine, which in the collapsed condition measured 292 cm. A lateral anastomosis was made between the remaining small intestine and colon. After some complications the patient recovered so rapidly that on the fourteenth day she was able to leave her bed, and some days later returned to her home. In the fourth week after the operation she passed successfully through a severe erysipelatous infection, accompanied by high fever and chills. She has not appeared to suffer from the removal of so large a portion of her intestine, has gained weight, and though the stools at first were mushy, of late they have been becoming formed.

Progress of Medical Science.

New York Medical Journal, June 23, 1906.

Joint Diseases, Especially Those of Childhood.—This topic receives a lengthy consideration from DeForrest Willard, whose main ideas are summarized in the following propositions: (1) Early diagnosis is the most important of all considerations. Physicians are responsible for a large majority of joint destructions, chiefly from carelessness or indifference in the examination of their patients. A child with any peculiarity of gait or carriage should be examined naked. (2) Every physician should abandon the thought that pain in a single joint in a child means rheumatism. A limp or peculiar gait, with rigidity of periarticular muscles, in a child always means some form of invasion, probably tuberculous, possibly septic. (3) Abort tuberculous in-

fection by immediate absolute rest and fixation of the joint. (4) Put the patient out of doors, day and night, for a long period of time. (5) Wise conservatism consists in the prompt application of all methods of relief, whether hygienic, mechanical, or surgical. In children conservatism should be the rule, since youth has remarkable recuperative power. In adults, however, operative measures are much fore frequently demanded. A limb that can readily be saved in a child, in the adult will demand amputation. If an operation will best accomplish a cure, such operation is true conservatism. (6) In septic cases following streptococcic, staphylococcic, pneumococcic, or gonococcic infection, open early and freely.

Digitalis and Barium Chloride.—M. R. Lamela reports a case which suggests that barium chloride is capable of replacing digitalis without the accumulative action of the latter, and without also its instant action on the gastrointestinal mucosa. His patient was a man of sixty years who had the usual sequence of polyarthritis and cardiac disease. On one occasion he took an overdose of digitalis and was pulled through with difficulty. Finally he arrived at the stage of orthopnea, nervousness, numbness of fingers, etc., and was put on one dram three times daily of a solution of barium chloride, gr. v to the ounce of water. After two weeks' treatment the pruritis disappeared, and later visible improvement was evident in the cardiac condition.

Bite of the Ombuta Treated with Potassium Permanganate.—F. C. Wellman reports the successful treatment of snakebite with the remedy named. The patient was a male negro in West Africa, who was bitten by the ombuta (*Clotho arietans*, Gray). The bitten area was excised, the wound filled with the crystals of the salt, while an aqueous solution of the latter was injected into the surrounding tissues. Alcohol was given freely. The wound sloughed, but at the end of a week it began to clear off and satisfactory granulations appeared. From this time on, the course was uneventful. The case presented the following distinctive features: (1) Loss of the coagulability of the blood after passing through the tissues at the seat of the bite. (2) Vomiting of blood (which, however, may have been due to violent retching), possibly from extravasations from the coats of the stomach. Such extravasations are attributed to the direct action of a special constituent of snake venom more abundant in the poison of the *Viperidæ* than in colubrine snakes. (3) Violent epistaxis. (4) Remote selective action of some ingredient in the venom, noticed by its effect on the respiration. (5) Sloughing of the site of the puncture, which cannot be attributed to the permanganate, as it is a common feature in snake wounds. (6) The stirring up of a latent malarial infection and the finding of parasites in the blood. (7) The complete recovery.

Journal of the American Medical Association, June 30, 1906.

Malarial Keratitis.—E. C. Ellett remarks that this disease, which consists in a branching linear ulcer of the cornea best manifested by staining with fluorescin, with variable surrounding infiltration, is an unusual complication of malarial disorders. It occurs most commonly in late summer and autumn, is never multiple, is very rare in the chronic forms of malaria, rarely occurs in both eyes, and not infrequently causes serious damage to the cornea. One attack predisposes to others, but not invariably. He believes that the lesions are probably trophic, and that they follow the nerve fibers of the cornea, and the fact that the corneal nerves lose their sheaths after penetrating about 1 mm. from the corneoscleral junction may possibly explain why the lesions never reach the edge of the cornea, but follow only the unprotected course of the nerves. As regards treatment, he says that the general condition should be looked after and a change of climate may be necessary. While he cannot say that he has seen striking results from quinine, it is nevertheless considered a necessary medication. Post-malarial anemia may call for iron, and blood examinations may be a valuable aid. Locally, an antiseptic wash and atropin should be always used and the eye protected. The most striking results will often follow the application of tincture of iodine, but this is very painful, even with cocainization and immediate irrigation, and is not always beneficial. Hot applications are useful and grateful to the patient. When the epithelium is regenerated, yellow oxide ointment or some similar preparation should be used to lessen the opacity. Refraction should be looked after and proper glasses supplied as needed.

Infantile Scurvy.—Alice M. Steeves reports two cases of infantile scurvy observed by her and describes the condition. She believes that the disorder is common in large orphan asylums and similar institutions, and in examining the mouths of 180 girls at the Lancaster Industrial School she found 20 per cent. with thickened, spongy gums, saliva purulent and mucoid, and with the nose, mouth, and throat inflamed. These girls all complained of having rheumatic pains, and while the condition, she says, is not strictly scorbutic, it seems to her to suggest a field for investigation.

Mounting Museum Specimens.—E. Albert describes his method of mounting pathological specimens in glycerin jelly. Like Coplin, he uses the ordinary Petri dishes, but he also adds stained microscopic sections of the tissues in the same Petri dish so that by placing the Petri dish on the stage of a microscope, the histological features corresponding to the gross characteristics of the specimen can readily be compared. The section, mounted between cover glasses, is attached to the under side of the cover of the Petri dish, at one side. If the cover is perfectly clear, as it should be, the section may be mounted directly on its inner surface with only the lower cover glass. An excess of glycerin jelly is used, so that when the cover is pressed down a little is squeezed out. After hardening is complete this excess is trimmed away and scraped out, and the whole sealed securely with gauze and paraffin.

Hypertrophy of the Brain.—J. H. Haberlin reports the case of a child, aged two, dying in convulsions, in which the apparently symmetrically enlarged brain weighed 1,712 grams (53 1-2 ounces). The membranes were not adherent, there was no flattening of the convolutions, no disproportionate increase in the size of the ventricles, and the gray and white matters were developed proportionately. Clinically, the case could not be differentiated from hydrocephalus.

The Lancet, June 16, 1906.

Metrorrhagia After the Menopause in Cases of Ovarian Tumor.—A. H. N. Lewers reports three cases. This symptom occurring at the time mentioned is generally regarded as evidence of malignancy in some part of the genital tract, but it is necessary to be sure in forming this opinion that the menopause has actually occurred. Of this fact we may feel reasonably sure if two years have passed without any mensstruation. Occasionally a postmenopause bleeding will occur without any morbid condition to account for it. Or we may be able to find some changes occurring in a uterine fibroid which has been quiescent for a long period, possibly a mucous polyp or even a subacute senile vaginitis, though the discharge here is generally yellowish, with the admixture of a little blood, and quite different from the actual hemorrhage of malignancy. Other possible causes are senile endometritis or ulcers on prolapsed tissues. The three tumors reported were two of multilocular cyst and fibroma, the corresponding ages of the patients being 60, 74, and 58 years. While, therefore, the appearance of a red discharge after the menopause should always excite suspicions of malignancy, and lead to a careful examination, yet it should be remembered that there may be other conditions to account for the discharge of a less threatening nature.

Intranasal Chancre Simulating Diphtheria.—J. D. Rolleston gives a brief summary of previously recorded cases and reports one personal case, his patient being a man of twenty-eight years, certified as suffering from nasal diphtheria. He had had diphtheria fourteen years before. One month before his first visit his nose became sore and began to swell. The right ala was thickened and tender, and lined with a membranous deposit, from which on pressure a serous fluid exuded. Left submaxillary and sternomastoid glands were considerably swollen and slightly tender. The throat appeared normal. There was on chest and abdomen a polymorphic rash, without pruritus. The nose was obstructed, and there was considerable right frontal headache. There was a very slight rise of temperature. Smears and cultures revealed no diphtheria bacilli. A diagnosis was therefore made of chancre from the objective appearance alone. The patient was placed on hydrarg. cum creta, two grains t. i. d., and the lotio nigra was freely applied to the nose. The beneficial effects of this plan were soon apparent, and in ten days the nose was nearly well. Other symptoms disappeared more slowly.

Examination of the Feces.—R. Baumstalk says that in trying to form an estimate of the capabilities of the intestine we must adhere to a special diet containing a necessary amount of calories and suitable proportion of the three principal groups of food stuffs. It must be taken readily, be digestible and agree well with even a disordered intestine. Coarse macroscopical fragments must not appear in the dejections and the diet must be

obtainable in any household. Such a diet is given in full by the author. The feces should then be examined macroscopically, microscopically, and chemically. Full details of the methods are given. The conclusions to be drawn from findings are then set forth. The author notes, among other facts, that the presence of connective tissue remnants in the test-diet stools points with certainty to a disorder of the digestion, as only the gastric juice is able to dissolve raw connective tissue, *i.e.* from the center and not from the well-cooked part of the meat. Achylia or hypochylia would usually be accountable for such a condition. Excessive peristalsis perhaps also plays an important part in some of these cases. Again, in excessive acidity associated with insufficient pepsin secretion (cases which not infrequently occur) the raw tissue meets with unfavorable conditions and appears again in the stools. A very minute examination of the stomach should be carried out in these circumstances. If muscle remnants are found macroscopically, or even in considerable amount microscopically, disturbance of the digestion in the small intestine may be inferred, for the stomach plays only an unimportant part in the dissolving of meat fiber, and the digestion of meat does not take place in the colon. With both connective tissue and muscle remnants in the stools, it may be concluded that both stomach and small intestine are deranged. Finally, he adds a few words in regard to the incubator test. After keeping the small fermentation tube (mentinoed under the head of chemical examination) in the incubator at 37° C., very little gas will be found under normal conditions. If one-third or more of the tube fills with water, that is pathological. It certainly betokens a morbid increase of carbohydrate fermentation if the reaction of the stools now tested once again is found to be strongly acid instead of being only feebly acid as before. It indicates degradation of the albumin when the reaction becomes more alkaline. When fermentation exists the feces usually assume a lighter color and smell of butyric acid; with decomposition, on the contrary, they become darker and have a very unpleasant smell. In the case of fermentation moreover, the formation of gases takes place more quickly and more freely, while with decomposition more slowly and more scantily. The signification of fermentation has already been explained above. Excessive decomposition of albumin occurs usually only in cases of severe diseases of the digestive tract, *e.g.* inflammatory changes of the mucous membrane of the colon, because it is especially the pathological products of the intestinal wall, mucus, serum, pus, which occasion putre faction, while merely functional disorders of the digestion of albumin seldom give rise to decomposition.

The Specific Nature of the Spirochetes of the African Tick Fever.—A. Breinl details a series of experiments in which the behavior of spirochætæ from the African tick fever was contrasted with that of similar organisms occurring in a case of relapsing fever occurring in New York City. The main portion of the paper is made up of the findings from various culture and inoculation experiments which cannot be well recapitulated here. The author concludes that the two organisms above referred to are of different species in that each confers a relatively active immunity against itself but not against the other.

British Medical Journal, June 16, 1906.

A Family Infected with Syphilis.—W. R. Grove reports the case of a girl who had contracted syphilis two years before giving birth to a female child. The mother had a few months' treatment. When the child was about 18 months old condylomata developed about the anus. Three weeks later the baby's grandmother, who had had the care of the child, developed a chancre of the lip. At this time a daughter of 12 years showed an initial lesion on the tonsil. Still later a young brother developed a similar lesion. The baby had lately been fed by spoon and, after the very common custom, the food had been tasted by the grandmother and the daughter, both of whom had fed the baby. The boy may have used the same spoon unwashed. The point emphasized by the author is the age of the child—eighteen months—before she infected others, and the consequent need of prolonged treatment necessary in all such cases. The entire family made a good recovery.

Pneumococcus Arthritis.—Another case (fatal) of this disease is reported by S. Raw, his patient being a man of 40 years who first had an ischiorectal abscess, the purulent contents of which contained *B. coli communis.* Several months later, after an alcoholic debauch, he developed pneumonia and a condition suggestive of acute sepsis, from which he seemed to be emerging when the right knee became swollen to such an extent that incision was necessary. Creamy "tuberculous" pus was evacuated which contained the pneumococcus. From that time on the man sank in spite of various stimulative measures and died about forty-eight hours after first appearance of joint symptoms.

Some Comparison of Phthisical with Nontuberculous Males.—This comparison is made by W. C. Rivers, chiefly with respect to healthy light-weight ratio and mouth breathing. He advances the following reasons in favor of the view that an hereditary causal relation to pulmonary tuberculosis may be predicated of mouth breathing and of deficient physique: (1) That both conditions prevailed to a much greater extent among consumptive males, quite independently of their disease, than among a comparable series of nontuberculous men. (2) That whereas some causes of mouth breathing, as also physical build, are known to be hereditary, a family history of phthisis is much more often given by those who are mouth breathers or of deficient physique—whether they be healthy or phthisical—than by others. (3) That the physique-incidence of mouth breathing in phthisical subjects probably differs from that in the nontuberculous. (4) That consumptives of a naturally good height-weight ratio fall ill, on an average, at a later age than do others.

Amebic Abscess of the Liver.—Two cases are reported by L. Rogers and R. P. Wilson. Both were cured by aspiration and injection of quinine into the cavity without drainage. Case 1 was one of very acute abscess, diagnosed by leucocytosis and the *x*-ray. Case 2 was one of repeated attacks of hepatitis culminating in abscess. Cure was rapid in both. The quinine solutions are prepared as follows: Two solutions are made up and sterilized before operation for aspiration, each containing 30 gr. of the bihydrochlorate of quinine, but in one this amount is dissolved in 2 oz. of water and in the other in 4 oz., the former being used if the abscess contains less than 10 oz. of pus, and the latter if it is larger. In this way the dose of quinine is limited to 30 gr., but in the case of larger abscesses it is dissolved in more water, so as to bring the drug into contact with all parts of the cavity. In Case 2, 50 gr. of quinine were injected, but the patient suffered from severe dizziness on coming round from the chloroform, so it appears advisable at present not to use more than 30 gr., which appears to be sufficient in practice. An objection which might be raised to considering the quinine injection as the cause of the rapid cure of these two cases of liver abscess is the possibility that aspiration alone would have been equally successful, as is very occasionally the case in tropical abscess of the liver. Apart from the extreme unlikelihood of two successive cases being so rapidly cured by aspiration alone, the author points out that the first case was a very acute one with remittent fever, which it is very difficult to conceive of as likely to be immediately cured by a single aspiration.

Berliner klinische Wochenschrift, June 11, 1906.

The Relations of Human Tuberculosis to that of Cattle.—Lydia Rabinowitsch discusses this subject from the standpoint of her own experimental work and of the observations of others, arriving at the conclusion that the *Perlsucht* baccilli of cattle are a source of danger to the human race. Numerous experimental observations in favor of this view are cited,—for example, the fact that in examining twenty strains of tubercle bacilli obtained from human beings two were found which, owing to their cultural peculiarities and increased virulence for rabbits must be regarded as bovine bacilli. In addition six of the strains were distinctly atipical, though their deviation from the ordinary human type was not sufficiently great to justify the conclusion that they were bovine organisms. The author sums up her views by saying that although the possibility of human infection through the bovine disease has been demonstrated, the gravity of this danger can as yet not be determined. The restriction of bovine tuberculosis is urgently required not alone from the standpoint of the agricultural interests but also on account of the danger to man involved. In fighting tuberculosis in man the first place must be given to the disseminated form and to consumption, and in this connection it is principally bacilli emanating from human beings that must be considered irrespective of whether the original infection was caused by human or bovine bacilli.

The Treatment of Obesity with Thyroid Extract.—Rheinboldt says that although this plan of treatment has fallen somewhat into discredit on account of certain undesirable features that sometimes attend it he believes that, properly employed, it is a very useful adiuvant to dietetic and other procedures. The unde-

sirable effects that have been noted may be ascribed to one of the following causes: There was an idiosyncrasy against the remedy, the dosage was incorrect, the preparation used was inert or contained toxic decomposition products, or the loss in weight was not entirely due to disappearance of fat but also involved destruction of body albumin. In order to avoid the first of these risks it is necessary in all cases to begin the treatment with the minimum dose. In most instances the treatment should be begun by the administration of one tablet per day, and the dosage is increased only when it is found that the amount being taken is not causing any decrease in weight. In general it may be said that more than seven or eight tablets a day should not be given, and it is also important to have the tablets well chewed. In order to avoid the danger of causing undesirable disturbances of body metabolism it is essential during the treatment to give the patient an excess of albumin in his diet. The overfeeding should be pushed to at least 3,000 calories and at least 20 per cent. of this amount should be composed of nitrogenous food, particularly meat. The use of thyroid extract imposes a grave responsibility on the physician, but is a distinctly valuable measure.

Münchener medizinische Wochenschrift, June 12, 1906.

The Treatment of Exophthalmic Goiter by Forced Feeding.—Alt presents a number of photographs to show the value of the dietetic treatment both of exophthalmic goiter and of cretinism. In both of these conditions he considers that the results to be obtained by overfeeding are of the greatest importance, though in order to carry the treatment out most effectively careful metabolism determinations are necessary. Caution is needed in planning the dietary in different cases, for the tolerance for carbohydrates is often quite restricted and the kidneys also are apt to be insufficient. He begins the treatment by giving a salt free diet, of which milk is the most important constituent, until the stored up chlorides have to a great extent been excreted and the existing edema has subsided. In continuing the treatment the salt of the diet is kept at about four grams per day, the amount of fluid is restricted, the carbohydrates are graduated in amount according to the tolerance, and the caloric value of the food is raised as high as possible by the use of albumin and fats. The latter are especially useful and are given in the form of milk, whipped cream, and unsalted butter. Under this régime the body weight increases, there is a subsidence of many of the characteristics of the disease, and increased functional capacity of the previously insufficient organs.

A Method of Ascertaining in One Hour the Amount of Albumin in Urine.—Buchner describes the following method which he says gives results sufficiently accurate for clinical purposes: Eight c.c. of clear unfiltered urine is placed in a graduated test tube and heated to the boiling point, two or three drops of nitric acid are added, and two c.c. of saturated solution of sodium chloride. The whole is then mixed thoroughly and is decanted into a specially graduated tube in which the precipitate is allowed to settle. Exactly at the end of an hour the amount of albumin may be read off directly. The author has controlled the test in a very large number of cases by the gravimetric method and with the Esbach apparatus, and concludes that it is accurate enough for ordinary work while it has the great advantages of simplicity and rapidity.

Deutsche medizinische Wochenschrift, June 14, 1906.

The Diagnosis of Typhoid Fever.—Poppelmann claims that after a little practice it is possible in every case of typhoid fever to discover the organisms in stained preparations of the blood by direct observation, and that the diagnosis may in this manner often be established at a period when the Widal reaction is still inconclusive. The technique he recommends includes the making of thick smears with blood obtained from the finger tip after this has been very carefully cleansed with ether and alcohol and sterile gauze. The slides also must be cleansed with great care and be sterilized by dry heat before use. The May-Grünwald stain is employed in the usual way. It is stated that the typhoid bacilli will always be demonstrable if the disease is typhoid fever. The organisms present great variations in their staining power and frequently appear to be on the point of undergoing complete degeneration. Fallacies to be guarded against are contamination of the preparation from the skin of the patient's finger and artefacts due to precipitates in the staining fluids, which are to be avoided by extreme cleanliness and filtration of the fluids respectively.

The Cure of Hysterical Contractures by Spinal Anesthesia.—Wilms describes a case of hysterical contracture of the musculature of the lower extremity in a man of twenty years, which made it impossible for him to walk without crutches owing to the complete fixation at the thigh, knee, and ankle joints. Under anesthesia the extremity at once became relaxed, but with the return of consciousness the rigidity returned. As a last resort spinal anesthesia was employed and the muscular relaxation that resulted was demonstrated to the patient. As soon as he had witnessed the complete mobility of the limb he was able to get up and walk himself unaided and no relapse has occurred.

Permanent Preparations of Urinary Sediments.—Wolff describes the following technique for this purpose. After centrifugalizing the urine, or obtaining the sediment by allowing it to settle in a conical glass the supernatent fluid is poured off and the fixing fluid, consisting of either 10 per cent. formalin followed by 90 per cent. alcohol, or the latter alone is added. If red blood cells are present it is preferable to use alcohol alone, as formalin destroys these structures in urinary sediments. The preparation is allowed to stand until the following day, when the supernatent fluid is replaced by alcohol and then by water if hematoxylin is to be used as the stain. If crystals are to be prepared, an alcoholic solution of the dye must be used, but for ordinary purposes double staining with hematoxylin eosin is the best. It is preferable to stain for twenty-four hours with weak solutions. After satisfactory staining has been secured the dye is replaced several times with water and the tube is allowed to stand for twenty-four hours longer. Five or six drops of concentrated alcoholic solution of eosin are added, followed in a few minutes by an excess of 90 per cent. alcohol. The sediment may now be preserved indefinitely in the alcohol or may be mounted in balsam by replacing with stronger alcohol, absolute alcohol, and carbolxylol. The preparations obtained in this way are said to be permanent and very clear.

Pathological Physiology of Seasickness. Attempt at Rational Therapeutics.—Chevalier, in describing seasickness, says that under the influence of the pitching and rolling of the boat the individual suffers from a series of abnormal reflexes by which the various nerves of the skin and viscera are disturbed. These various impressions are elaborated in the nervous centers and, being reflected to the various organs of the body, give rise to distinct disturbances. Pampoulais has shown that seasickness is the result of cerebral anemia, which is provoked by various causes, chief among which he ranks the cerebellar disturbance. Seasickness, then, may be said to be a combination of the central nervous system, of the pneumogastric, of the splanchnic, and of the phrenic. —*La Presse Médicale,* May 16, 1906.

Foreign Body in the Myocardium.—M. G. Leven reports the experiment performed on a dog by which he demonstrated that a foreign body was retained in the heart muscle for some time without apparent disturbance. A glass pipette was introduced into the heart. The end was then broken off. No attempt at asepsis was made. The object was left for five months in the myocardium, but the dog did not appear to suffer from its presence. After death there was found a very small patch of pericarditis on the visceral side of the serous membrane. The fragment of glass, which was about one centimeter long, had penetrated the anterior wall of the left ventricle without entering the ventricular cavity.—*Bulletins et Mémoires de la Société Anatomique de Paris,* December, 1905.

Trophic Nervomuscular Lesions Produced by the X-rays.—F. P. Sgobbo records the case of a patient treated for a localized syphilitic lesion of the lip and cheek by the *x*-rays, in whom after a time there developed a neuritis with an atrophy of some of the facial muscles as a result of the treatment. This was shown by a careful electrical examination, which showed that the affected muscles presented a slowness of response to galvanic and faradic currents with a reversed electrical formula, and that there was a trophic alteration of the nerves and muscles. These alterations could not have been due to the syphilitic process, because they were not confined to the area of this manifestation. The author believes that we should admit that the rays may affect parts of the body at a distance from the area treated and should exercise proportionate care in treatment, because such lesions come on slowly and are progressive.—*Giornale di Elettricita Medica,* March and April, 1906.

Book Reviews.

PROGRESSIVE MEDICINE. A Quarterly Digest of Advances, Discoveries, and Improvements in the Medical Sciences. Edited by HOBART AMORY HARE, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College, Philadelphia; Assisted by H. R. M. LANDIS, M.D., Assistant Physician to the Out-Patient Medical Department of the Jefferson Medical College Hospital, March 1, 1906. Philadelphia and New York: Lea Brothers and Company, 1906.

THIS quarterly review is now so well known that it is only necessary to announce the appearance of the new volume, and to state its contents. The present issue contains sections on the surgery of the head, neck, and thorax, by C. H. Frazier; on infectious diseases, including acute rheumatism, croupous pneumonia, and influenza, by R. H. Preble; on the diseases of children, by F. M. Crandall; on rhinology and laryngology, by D. B. Kyle; and on otology, by B. A. Randall. The *résumés* of all the important articles in medical literature, and the critical remarks of the various contributors, together constitute a most readable and valuable review.

THE OPERATING-ROOM AND THE PATIENT. By RUSSELL S. FOWLER, M.D., Surgeon to the German Hospital, Brooklyn, N. Y. Fully illustrated. Philadelphia and London: W. B. Saunders Company, 1906.

THIS book is intended to serve as a guide to operating-room nurses and hospital internes and presents a great deal of useful information in concise form. It opens with a description of the operating room and its personnel and the duties of the latter from chief nurse down to orderly are described in considerable detail. The instruments and the supply room are considered in the following two chapters, but as this constitutes one of the most essential features of the nurses' work, the descriptions might have been somewhat less brief. Although the book is excellent in many respects, faults of both omission and commission are unfortunately numerous. Boiling is the only manner in which instruments may be sterilized according to Fowler, as no mention is made of any other, and this also applies to rubber gloves. Boiling the latter and then immersing them in bichloride solution is a method to be reserved for emergencies and will be found but rarely practised in well regulated hospitals. The subject of anesthesia is quite fully discussed, but no mention is made of ethyl chloride, which is now so extensively used. The preparation of the patient is fully discussed and also the post-operative treatment, but along with the latter it would have been wise to present a more extended description of shock and secondary hemorrhage, two extremely important topics about which a nurse and a house doctor ought to be well informed. The errors mentioned and some others will probably be corrected in a second edition, for in other respects the book is deserving of favorable attention.

THE COMPANIONSHIP OF BOOKS AND OTHER PAPERS. By FREDERIC ROWLAND MARVIN. New York and London: G. P. Putnam's Sons, 1905.

EVERY page of this charming work of Dr. Marvin bears witness to the scholarly mind, studious habits, and at the same time, facile pen of the author. This is a good book for the professional man to take away with him on his summer vacation, and on his return home it can be added to the literature on his waiting room table. The various papers contained in the volume are all more or less interesting; they cover a wide range of subjects, and will appeal to thoughtful persons.

A TREATISE ON SURGERY. By GEORGE R. FOWLER, M.D., Examiner in Surgery, Board of Medical Examiners of the Regents of the University of the State of New York; Emeritus Professor of Surgery in the New York Polyclinic, etc. Volume I. Philadelphia and London: W. B. Saunders Company, 1906.

THE gifted author of this work, who succumbed to the very disease in the treatment of which he was considered an authority, was well fitted by experience and temperament to produce a work which would be characterized by novelty and general excellence. The present volume, which is shortly to be followed by another, deals with the general principles and also with the regional surgery of the head, neck, and thorax. In the first part of the book the arrangement varies somewhat from that ordinarily followed in other text books; the subject of surgical bacteriology, for example, is introduced in connection with the etiology of inflammation, of which it is, of course, an important factor. The increasing interest and value of hematology, urinology, and other kindred subjects in their bearing on general surgical diagnosis has prompted the incorporation of a separate section on these topics, which has been written by Dr. F. E. Sondern. A comprehensive view of this subject is afforded within the limits of this chapter, which is thoroughly practical and up to date, although much in it was necessarily sacrificed to brevity. The subject of surgical anesthesia is discussed and the chapter on operative technic is very satisfactory. An evidence of the up-to-date character of the work is shown in the chapter on gun-shot injuries, where the experience with the modern weapons gained in the recent Russo-Japanese war has been drawn upon for purposes of illustration.

In the practical portion of the work, the anatomical method has been followed and in the present volume there is included the surgery of the head, the neck, and the thorax. These subjects are satisfactorily treated in most respects, but some wonder may be expressed why no greater space is given to such an important topic as the surgery of the brain. A great deal of attention is given to the various plastic operations on the head and face. The differential diagnosis of every surgical condition is fully treated as are the etiology and pathology, and another feature of interest is the paragraph of historical reference which is included in each chapter. As for the general make-up of the book, nothing seems to be wanting. The illustrations are scattered throughout the work and are with few exceptions entirely original. They are superior to those of most textbooks. The appearance of the second volume of this treatise will be awaited with interest, for this takes up the surgery of the abdomen, a field in which Dr. Fowler did much original work and with which his name is particularly associated.

KLINISCHE UND ANATOMISCHE UNTERSUCHUNGEN ÜBER DEN CRETINISMUS. Von Dr. WILHELM SCHOLZ, Privatdocent in Graz. Berlin: August Hirschwald, 1906.

THE author is an inhabitant of that section of Europe where cretinism is practically endemic, and was led to a closer study of the subject from his constant contact with the disease. His researches deal more particularly with clinical and statistical facts based on a large number of cases, together with measurements of body, skull, and face, *x*-ray examinations, pathological conditions, and metabolism. Scholz is inclined to the belief that improved hygienic and social conditions will exert an important bearing in eliminating or at least in holding the disease in check. The badly degenerated types will be unable to procreate and the influx of new blood by immigration will, he thinks, aid in overcoming the tendency to transmit the milder types of the disease. He does not appear to be impressed by any therapeutic measures which have thus far been advocated. The book is very complete and will be of undoubted value to those directly interested in this subject.

L'INJECTION TRACHÉALE SIMPLIFIÉE. Par le Dr. HENRI MENDEL. Paris: F. R. De Rudeval, 1906.

THIS monograph is an exploitation of the author's method of giving injections by holding the cannula of the syringe against one lateral pharyngeal wall and discharging the fluid against the opposite wall, whence it runs down into the larynx and trachea. He contends that when the tongue is held as in ordinary laryngoscopy, the pharynx forms a funnel of which the only outlet is the larynx unless the patient attempts to swallow.

MANUAL OF DISEASES OF THE EAR, NOSE, AND THROAT. By JOHN JOHNSON KYLE, B.S., M.D., Clinical Professor of Otology, etc., in the Medical College of Indiana. Philadelphia: P. Blakiston's Son & Co., 1906.

SO many manuals have appeared during the last few years in this special department of medical literature that the reviewer has difficulty in not repeating his former observations. Suffice it to say that the present volume is printed on good paper, with clear type and good illustrations, is handsomely bound, and of a handy size and shape. So much for the vehicle. As to the contents, we believe that Dr. Kyle has prepared one of the most useful manuals that has fallen into our hands. First of all he makes free acknowledgment of the older and more pretentious treatises and then shows himself a careful gleaner in the field of current literature. His methods of treatment he confesses are somewhat dogmatically expressed, but he properly justifies this position by saying that his statements are the convictions resulting from his own experience. The table of contents is well subdivided and the index renders ready reference possible. We are somewhat surprised to find the following statement under the heading of general anesthesia: "In the removal of tonsils and adenoids, a general narcosis is exceedingly dangerous; the pain of operation in children is so small as compared with the greater danger of the anesthetic that only in exceptional cases should other than a local anesthetic be used." He considers that in adenoids the A. C. E. mixture is the safest general anesthetic to use. We do not believe, however, that his general proposition meets with the approval of the majority of those who work in this special field.

Society Reports.

AMERICAN MEDICAL ASSOCIATION.

Fifty-seventh Annual Meeting, Held in Boston, June 5, 6, 7, and 8, 1906.

(Special Report to the MEDICAL RECORD.)

(*Continued from page 1065, Vol. 69.*)

SECTION ON OBSTETRICS AND GYNECOLOGY.

Third Day—Thursday, June 7, 1906.

DR. C. S. BACON OF CHICAGO IN THE CHAIR.

Manual and Instrumental Dilatation of the Gravid Uterus.—Dr. J. CLIFTON EDGAR of New York read this paper. He said the graver obstetrical operations find their necessity in the difficulty or impossibility of overcoming the barriers to delivery by the natural passages, viz., the resistance offered by the bony pelvis, and the obstruction of the cervix. He believed unfortunate results for both mother and child were far more often the consequence of nondilatation or unsatisfactory dilatation of the cervix than of obstruction offered by the bony canal. The various mechanical devices for cervical dilatation, cervical incisions, and vaginal cesarean section were all applicable in appropriate instances and no method should be condemned without a trial. Clinically he divided his cases in which manual or instrumental dilatation of the pregnant or parturient uterus was demanded into those calling for rapid dilatation (within an hour), and those where more time was available for removal of the cervical barrier. Rapid dilatation could be accomplished by incision or mechanical dilatation, the former including cesarean section and deep cervical incisions. After the thirtieth week of gestation mechanical means for rapid dilatation would suffice in most cases, incision of the cervix being rarely called for. He had cut very few cervices since the introduction of the Bossi dilator. Receding from the thirtieth week of gestation, the number of cervices that could not safely be rapidly dilated by manual or instrumental means increased. Bimanual stretching of the cervical sphincter—which he had practised in cases of eclampsia, placenta prævia, and delayed labor since 1892—had proved very satisfactory. If difficulty were experienced in inserting the second finger, it was his routine practice to resort to preliminary dilatation with the Bossi dilator. He had failed to find any advantage in the two-bladed dilator of Gan or the latest type of Harris' dilator that the Bossi did not possess. He had found the Bossi dilator invaluable in cases in which much resistance was encountered because of the nondisappearance of the supravaginal cervix, and in which time did not allow the preliminary use of the hydrostatic bag. Ten or fifteen minutes' use of this dilator would set up uterine action in such cases, and consequent drawing up of the internal os; it would also cause softening of both rings of the cervix, relaxing them sufficiently to permit a safe and rapid manual dilatation. He never used the Bossi dilator to complete the effacement of the cervix. For slow dilatation of the cervix he relied chiefly on the hydrostatic bag of the Champetier de Ribes type. He had found the solid uterine bag to act in the same way, but to a less extent. Both the hydrostatic bag and the solid bougie acted more promptly and energetically in primiparæ than in multiparæ. He had often employed them as a preparatory means to be followed by manual dilatation, with the patient anesthetized. Artificial delivery was then accomplished or the case left for spontaneous expulsion.

Instrumental Dilatation of the Parturient Uterus.—Dr. FRANKLIN S. NEWELL of Boston in this paper gave as the general indications for instrumental dilatation, hemorrhage, the toxemias of pregnancy, and the conditions complicating toxemia. The hand was the best dilator which had been discovered, and was to be preferred to any other instrument in proper cases. Its usefulness, however, was limited by the fact that it was easily exhausted. In cases of marked rigidity the hand was inefficient. Safe dilatation depended upon the recognition of the fact that the cervix was made up of strong muscular tissue which had to be tired out. In view of the fact that the hand was capable of exerting pressure for only a limited time, it was necessary to dilate partially before the hand was used at all, hence manual dilatation was of limited value. In most cases of placenta prævia the hand was the best dilator Unintelligently applied, it became a source of danger. In many cases in which manual dilatation was impossible, or possible only after dangerously prolonged operation, instrumental dilatation was useful. Many instruments had been devised for this purpose. The elastic bags had a limited field of usefulness. In placenta prævia and broken heart compensation the action of the bags was too slow to be satisfactory; in eclampsia they were contraindicated. The first satisfactory dilator was the Bossi dilator, which possessed many advantages. It also possessed certain distinct disadvantages. It was too powerful, and it was impossible to control the force. The ideal dilator was one which, while capable of accomplishing the work, was under the control of the operator. Dr. Newell demonstrated such a dilator which he had devised. With this instrument the cervix could be dilated to three-quarters dilatation with no more danger than if dilated with the hand.

Dr. HARRIS of Paterson, N. J., said he had never placed a woman on the operating table without effecting dilatation with the hands. Every physician should know a hand method of dilating the cervix. His own method consisted of the introduction of the hand into the vagina. If the vagina were too small to admit the hand, or the head had entered the vagina, thus preventing the entrance of the hand, this method could not be used. His method could not be used unless the first finger could be introduced to the metacarpophalangeal knuckle. It required from one-half to one and one-half hours to dilate the cervix to the circumference of eleven or twelve inches. The head would then pass easily, so that the time of labor was taken up with the manual dilatation. The personal factor entered into the question.

Dr. BOYD of Philadelphia thought it would be a step backward to lay too much stress upon instrumental methods Manual dilatation had served him so well that he wished to defend that method. Any or all of the instruments described would be of service to dilate the cervix to probably the degree of one dollar; beyond that the cervix would very often tear with the use of instruments. He would use instrumental dilatation of the cervix to the size of a quarter or a half dollar, completing the operation by manual dilatation or incision.

Dr. STOLTZ of South Bend, Ind., said he had found manual dilatation a most trying ordeal to both operator and patient. He had used the Bossi dilator with good success. After it was inserted he put the finger in between the blades, really dilating with the finger. As dilatation proceeded he inserted two fingers between the blades. The dilator was so constructed as to give an excellent fulcrum upon which to use the knuckles. He used the dilator merely to take up the slack. In that way the dilatation is done as much with the hand as with the dilator.

Dr. HASTINGS of Toronto, Canada, said a hard and fast line should be drawn between where skilled obstetrics ended and meddlesome midwifery began. Not so much depended upon the method as upon the operator. If one went slowly, making, say, a quarter of a turn a minute, dilatation could be accomplished with properly curved instruments with comparatively little danger. Danger arose from rapid dilatation with an instrument not properly curved. The great disadvantage with manual dilatation lay in the fact that the hand readily became powerless. The hand should not be the source of great infection, because no case of obstetrics should be attempted with the ungloved hand.

Dr. PADDOCK of Chicago deprecated the use of instruments. He thought the dilator was used too frequently. In a

considerable practice in obstetrics he had found but one case in which it was necessary to use any dilator other than the hand. Any of these instruments were dangerous in unskilled hands. He would prefer the instrument presented by Dr. Newell.

Dr. Dührssen of Berlin, Germany, advocated vaginal cesarean section. He had repudiated the Bossi method entirely, considering it dangerous. It led to tears which endangered life. In cases of rigid cervices there was a lack of elastic fibers, and dangerous tears resulted from attempts at dilatation. In such cases it was possible to dilate by incision. He thought cesarean section could be performed in the home as well as in the hospital by the skilled operator.

Dr. von Rosthorn of Heidelberg, Germany, said that in Germany obstetricians were divided into two groups, one recommending incision and the other dilatation. He had employed the Bossi method, slowly, as recommended by Bossi himself, and had had no failures. He had also had experience with vaginal cesarean section, worked out by Dr. Dührssen. In Germany the majority favored the incision or vaginal cesarean method. It was a surgical method, and by it the operator could know exactly what he was doing, and it should be employed in cases in which it was necessary to act quickly. When there was plenty of time the balloon method, which was sure and not at all dangerous, could be employed.

Dr. Boardman of Boston wished to go on record as being still in favor of manual dilatation. He had opposed the dilating instruments except in the hands of experts. The skillful operator could employ the incision method with perfect safety, but for the mass of practising physicians he did not advocate its use. No instrument could have the intelligence of the human hand, which was an important factor. He disposed of the question of infection by the manual method by advocating the use of gloves.

Dr. Carstens of Detroit considered the operation advocated by Dr. Dührssen a simple one, though some present seemed to think it a difficult one. By separating the bladder from the uterus, making an incision of, say, two inches, without opening the peritoneum, keeping well in the median line, the child could be delivered by version or forceps in six or seven minutes, with very little hemorrhage. This was necessary only in cases of uremic convulsions.

Dr. Yanos of Chicago said that the obstetrician should be prepared to employ any method. It was rare that it became necessary to use the incision method, but when it was necessary every obstetrician should be able to do it. It was very simple in reality. The Harris method of manual dilatation was a most excellent one. She recommended the combined instrumental and manual dilatation.

Dr. Edgar said he had never seen a branched dilator that would not tend to slip after two-thirds dilatation of the cervix had been accomplished. He believed the dilator presented by Dr. Newell was a radical advance over all others, particularly as the hand did the dilating. With the Bossi dilator the amount of force could not be estimated, as could be done with the hands or with the Newell dilator. He believed the case to be rare which would resist manual or instrumental dilatation, or a combination of the two, but in some instances it would be necessary to resort to vaginal or suprapubic cesarean section. The method advocated by Dr. Dührssen was useful, but was employed by him less frequently than it was a few years ago.

Dr. Newell agreed with Dr. Edgar with reference to the slipping of the terminals after two-thirds dilatation with the instrument. He thought more babies had been sacrificed by the operator's hands being tired than had been injured by the use of instrumental dilatation. Vaginal cesarean section in cicatricial stenosis was necessary. He thought the earlier it was realized that obstetrics was a surgical condition the better for the community as a whole.

Vaginal Celiotomy.— Dr. Dührssen of Berlin, Germany, read this paper. He reviewed the work of the American pioneers in this line, and gave the history and technique of the operation devised by himself. He had performed 1,593 vaginal celiotomies. In the first 900 cases the mortality was 3 per cent. The mortality of all cases was 2 per cent., and was due to fibroids and pregnancy.

The Best Method of Closing Aseptic Wounds, Especially Those of the Abdomen.—Dr. Henry O. Marcy of Boston presented this subject. Despite the recognition of the importance of incorporation of the peritoneum within the sutures, and of the advisability of including a considerable amount of the tissues within the grasp of the ligature, failures of this method were of constant occurrence. A careful analysis of the parts to be rejoined would make the explanation of these failures easy. The experience of many operators was confirmatory of the views which he had advocated for years concerning the advantages of the buried animal suture. He had emphasized the importance of the accurate readjustment of the sundered structures in all parts of the body, but particularly in the abdominal wall, which must be expected to resume its normal function and to be kept for the rest of life in a state of more or less active tension. The possibility of closure in layers was dependent upon the use of buried sutures. Silk for this purpose should be discarded. The suture material must be aseptic and absorbable, and the tendon suture most nearly answered these requirements. The peritoneum should be carefully coaptated, preferably by the use of the so-called shoemaker's stitch, a double continuous suture. The sutures should not be drawn too tightly. The post-recti fascia should be included in the peritoneal suture. The muscle fibers need not be reunited unless there was bleeding or injury due to undue manipulation. The thick anterior fascia should be carefully reunited. Each line of coaptation was closed upon its independent plane. As a rule the fatty layer required no suture, a careful coaptation of the skin usually holding the fatty layers in apposition. The skin was preferably closed by a continuous suture. The deeper layer of the skin only should be penetrated by the suture, since a micrococcal infection might easily follow if the sweat ducts or hair follicles were penetrated. The so-called subcuticular stitch should be called the subglandular or subfollicular suture. The suture material should be fine and not too highly chromicized. The reduction of scar tissue to the minimum was important. He did not advocate the use of wound drainage in the after-dressing, but used the collodion seal devised by himself, modified by the incorporation of iodoform. This seal adhered so closely that it did not permit the escape of the subcuticular fluid, and was germ-proof. A wound aseptically made and maintained, in aseptic and well-vitalized structures, would heal by primary union. Dr. Marcy presented specimens of kangaroo tendon and told of its preparation and care.

Dr. Ferguson of Troy, N. Y., said Dr. Marcy had spoken of getting below the glands of the skin and of the subcuticular stitch penetrating the deeper layers of the skin. He had seen Dr. Marcy operate and knew that he put the suture into the network of fat and missed the deeper glandular structures which sometimes penetrated the whole skin, and in which lurked the germs. He had lately pretty largely discarded the seal, since he had reason to believe that adhesive plaster could be made aseptic. He applied the plaster gridiron fashion.

Dr. Clarke of Cambridge, Mass., advocated Dr. Marcy's method. The wound must be aseptic and kept so. Properly employed it left a hardly perceptible scar.

Dr. von Rosthorn of Heidelberg, Germany, said that in Germany there was no more discussion of how to close the abdominal wound—the tier method was always used. In the Bassini operation the layers were divided according to their anatomical situation, and in closing the wound were sutured one after the other. As a prophylactic measure to prevent abdominal hernia, the same tier method should be employed. This method had been used in Ger-

many for about twenty years. The dressing was as simple as possible, with a little iodoform or sterile gauze held in place not by adhesive bands, but by the paste described by Dr. Schleich. Exact research carried on in Germany had shown that ventral hernia took place only when suppuration occurred, and not when the wound healed by primary union. He agreed with Dr. Marcy as to the suture material to be used. He used catgut for the deeper layers and silk when catgut would be absorbed too quickly, thus allowing rupture or fissure. Otherwise he deprecated the use of silk. Another method employed in Germany consisted in putting clamps upon the skin superficially. Drainage, complicated dressings, bandages, etc., had all been abandoned in Germany.

Dr. Goelet of New York said two results were to be accomplished in closing the abdominal wound—to make a strong wound and to make a nice looking wound. To accomplish this, attention must be paid to the uniting of the different layers and to the suture material employed. Dr. Marcy deserved great credit for popularizing the subcuticular method, whereby a very strong wound and a very nice looking wound could be obtained. The suture material must be not only aseptic but antiseptic. For some time he had been using iodin-treated catgut. This was immersed in iodin or iodide of potassium for eight days. It was strong and could not be infected, and would last long enough for primary union. In uniting the peritoneum he included the lower border of the muscular structure of the abdominal wound, and with the fascia the upper border of the muscle. If abundant, he united the fat with a loose continuous suture, and the skin with a subcuticular suture.

Dr. Stoltz of South Bend, Ind., thought it advisable not to make an edge-to-edge suture of the peritoneum, but to bring the edge up, making a running suture. He also advocated overlapping the transversalis aponeurosis, just as Andrews had done in inguinal hernia.

Dr. Reynolds of Defiance, Ohio, advocated the use of adhesive plaster after the tier method of suturing.

Dr. Straus of New York called attention to the method of making the section in different planes, which was advantageous in the event of suppuration, which would sometimes occur. He used kangaroo tendon.

Dr. Dührssen of Berlin said he used the method advocated by Dr. Marcy. Instead of making the incision in the median line he made it to one side. The inner side of the fascia was stripped off from the muscle to the median line, and the muscle separated in the median line. With primary union hernia was impossible with this method. Iodin catgut was employed to great advantage.

Dr. Dorsett of St. Louis emphasized the importance of not using too large sized animal tendon. Ligatures should not be tied too tight. Many men used through-and-through sutures with just as good results as could be obtained by the other method.

Dr. Marcy emphasized the fact that no matter what method was employed, it should be done correctly. He had tried the eversion and overlapping methods, and had found eversion with double suture the best. He detailed the preparation of catgut suture material, and showed how every process of disinfection was one of injury to the connective tissue of the suture.

Uterine Myomata Complicated with Pregnancy, with Cases.—Dr. E. E. Montgomery read this paper, in which he asserted that growths of the submucous or interstitial varieties predisposed to sterility because of the accompanying endometritis. Subperitoneal and interstitial growths not encroaching upon the cavity of the uterus did not preclude conception. The occurrence of pregnancy increased the danger of the patient, because of the more rapid growth of the tumor, the possibility of its becoming impacted in the pelvis, pressure upon important organs, increased probability of interruption of the pregnancy, and the greater susceptibility of the patient to saprophytic or septic processes following delivery. For these reasons it was better that such a patient should be subjected to operation prior to the occurrence of pregnancy. The character of the operation would necessarily depend upon the age of the patient, the number, size, and situations of the growths. In women under thirty-five years of age, where it was possible to retain a functionating uterus, it should be done. He cited a case to show that extensive cicatrization did not necessarily preclude the successful process of gestation. The conditions which would justify interference after pregnancy were the following: (1) Persistence and more or less continuous pain over the abdomen. (2) Such rapid growth of combined tumors in the uterus that the life of the patient was in danger from pressure upon vital organs. (3) Such a situation of the growth as would make it a positive obstruction upon the completion of pregnancy. (4) Indications, hemorrhagic and otherwise, that abortion or premature labor is impending. Hysterectomy, either complete or partial, would be the operation attended with the least mortality for the mother, but absolutely doomed the other life and precluded all hope for offspring, consequently should be accepted only when there was no hope for the continuation of pregnancy, or when alternative measures were absolutely contraindicated. The enucleation of fibroids was not necessarily attended with the termination of the pregnancy, as shown by three cases in which this was done, the patients continuing to full term.

Dr. Clarke of Cambridge said that a few years ago he had collected the results of one thousand deliveries to learn the outcome with reference to the mother and the child, and he did not recall a single accident to the child. It was surprising how many pregnant women went on well with large myomata unless the tumor took on rapid growth. He limited operation in these cases to subperitoneal myomata with long pedicles and to rapidly growing tumors.

Dr. Boldt of New York, referring to the liability of abortion following myomectomy during the period of gestation, said his experience was that pedunculated tumors and those situated subperitoneally were not likely to produce abortion. Those situated interstitially were apt to do so. No matter how much appearances might lead to the probability of obstruction from the tumor during confinement, there was a likelihood that at the end of gestation nature would provide some way by which the tumor would be displaced so that delivery would take place spontaneously.

Dr. Tuttle of Cambridge cited two cases which he had recently had of uterine fibromata complicating pregnancy, in which removal of the tumors excited no contractional pains, both women going on to term.

Dr. Benjamin of Minneapolis said the indications for operating on these cases were pain, the location of the tumor, and the symptoms of degeneration. Many of these patients would complain of more or less severe pain, with symptoms of abortion. He cited two such cases upon which he had operated without any particular trouble.

Dr. Carstens of Detroit laid down the simple rule that if the tumor was at the fundus it should be left alone; if down low, it should be enucleated; if in the posterior cul-de-sac and adherent, it should certainly be operated upon.

Dr. Frederick of Buffalo agreed with Dr. Carstens that fibroid tumors below the ileopectineal line, if seen early enough, should be enucleated; if the woman went to term in such case Cesarean section should be resorted to.

Dr. Dorsett of St. Louis, referring to the rapid growth of fibroid tumors, cited a case in which he opened the abdomen, intending to do an enucleation, but the tumor was pushed down and filled the whole cavity of the sacrum. He did not try to remove the tumor, the woman went on to full term, and the tumor seemed to undergo involution with the uterus.

Dr. Porter of Fort Wayne, Ind., said that in addition to mechanical irritation the presence of fibroid tumors greatly increased the chance of sepsis after delivery. The location of the tumor was not the indication for its removal, but whether or not it would interfere with the woman's recovery after delivery.

Dr. Montgomery agreed with those who advocated non-

interference unless there were absolute indications for interference. If the patient suffered no inconvenience from the too great size of the tumor, she should be allowed to go on to the completion of her pregnancy, because in the end cesarean section could be resorted to if necessary.

Pregnancy and Labor Complicated by Anterior Fixation of the Uterus.—Dr. George M. Boyd of Philadelphia read this paper. In 1886 ventrofixation was welcomed as a positive means for curing the retroverted uterus. The uterus was firmly fixed to the anterior abdominal wall, and all went well until complications to pregnancy and labor developed. These complications varied from bladder irritation and bladder pains to abortion, dystocia, and obstructed labor. Various modifications of the method were devised, all having the purpose of obviating the dangerous complications of future pregnancies. Ventrosuspension obviated the difficulty in some cases, but did not prove satisfactory in others, and surgeons were still divided in their opinion as to the merits of ventrofixation and ventrosuspension. He reviewed the complications met with and their treatment.

Dr. Warren of Portland said that after thirty-two years of obstetric experience he had just had his first case of rupture of the uterus. It followed the classical course of labor, complicated by fixation, beginning with the escape of the waters, followed by severe pain in thirty-six to forty-eight hours. No presenting part could be felt, the cervix could not be felt. His advice was to open the abdomen and free the adhesions or after opening the abdomen to empty the uterus. Finally the head appeared in the lower strait, occipitoposterior position. Terrific hemorrhage followed delivery. The child had delivered itself through the rupture.

Dr. Bovée of Washington said this subject of fixation or suspension was an obsolete one. It was an absolutely illogical operation, and one should not be surprised to hear of accidents following it.

Dr. Frederick of Buffalo believed it to be illogical during the child-bearing period. He protested against suspension. In 50 per cent. of cases it did not suspend the uterus at all.

Dr. Lawrence of Columbus, Ohio, reported two cases of obstruction of the bowel following ventrosuspension, in which the loop of bowel passed over the drawn-out attachment of the uterus and became strangulated. The operation devised by Bovée of shortening the retrosacral ligaments was much more logical.

Dr. Boyd said, in closing the discussion, that when the patient was found with the cervix high up in the pelvis, with a large mass obstructing the outlet, with no attempt of the head to descend, even under anesthesia, the condition was a serious one. In such case the operator should be governed by the position of the cervix and the position of the fetus. If in the later months of pregnancy the head was found dipping into the pelvis, the case might go on without complications; if the cervix was high up, however, this would probably not be so. He did not approve of premature labor.

Hand Disinfection.—Dr. Herman J. Boldt of New York read this paper, in which he called attention to a method of hand disinfection which was more certain, more agreeable, and cheaper than the methods now in use. The ideal condition was absolute sterilization, which was as yet not attained. Three methods were in use: Fürbringer's, by means of hot water, alcohol, and mercury bichloride; Kelly's method, requiring potassium permanganate and oxalic acid, and the third, the use of chloride of lime and sodium. All were imperfect. Landrer and Kramer had shown that scrubbing the skin with soap, ether, and some antiseptic solution acted only on the surface of the skin, and it was later shown that often after so-called sterilization more germs could be obtained from the hands than before the disinfection was attempted. In 1886 Loew and Fischer called attention to the disinfecting power of formaldehyde. Recent experiments had discovered a process by which all difficulties heretofore attached to solutions of formaldehyde had been overcome. The process consisted in dissolving the gas in a solution of absolutely neutral soap. The formic acid decomposed part of the soap and combined with the alkali, leaving the fatty acid free; by filtration a clear, stable solution of pure formaldehyde in soap was obtained. This gave a solution which was more efficacious than all others, and from it all irritating properties had been removed. This antiseptic would do all that any others would do, and more. It destroyed germs and spores more quickly than any other antiseptic, and would penetrate and kill microbes where no other form would reach. It did not roughen the hands nor harden the skin, was non-irritating, and left no unpleasant after-effects.

Dr. Carstens of Detroit had never used this method of hand disinfection, but would not agree with Dr. Boldt that the older methods were so inefficient as would be inferred from the paper.

Dr. Lawrence of Columbus, Ohio, advocated simple measures for cleanliness. He saturated the skin to be disinfected with turpentine, which dissolved out the fats, then used soap and water. He had never had any unsatisfactory results.

Dr. Boldt said that any man connected with a large surgical service would sooner or later have an abscess, which would indicate to him that there was something wrong. There was no such thing as an absolutely clean hand from a surgical point of view.

The Stem Pessary for Amenorrhea and Dysmenorrhea. Some Further Observations.—Dr. J. K. Carstens of Detroit summed up his conclusions on this subject as follows: First, the stem pessary would generally cure amenorrhea after all other means had failed. Second, it would develop an infantile uterus and enlarge a prematurely atrophied one, and would restore a superinvolutional womb to a normal condition. Third, it would cure most cases of intractable dysmenorrhea in which no special pathological condition could be found. Fourth, if worn for six months or a year it would sometimes cure sterility. Fifth, all inflammatory conditions about the pelvic organs must be rigidly excluded before its use, and proper antiseptic precautions should be observed in its introduction.

To What Extent Can the Gynecologist Prevent and Cure Insanity Among Women?—Dr. W. O. Henry of Omaha read this paper. He held that the intimate connection between pelvic disease and insanity in women had not received due consideration from alienists or gynecologists. The profession and the laity should understand that any irritation too prolonged in subjects of certain types would prove an important link in the long chain of causes leading to a mental upset. Alienists and gynecologists should cooperate in removing these pelvic sources of irritation before insanity occurred. By such cooperation 75 to 80 per cent. of the women who now became insane would be saved from this calamity, while 60 to 70 per cent. of those already insane might thus be cured.

Dr. Manton of Detroit said that in an analysis of several thousand cases he could not find a single case in which it was apparent that the mental disorder was due to pelvic disorder. He did not believe the relation of pelvic disorder to insanity as great as Dr. Henry seemed to believe. Insane women should be given the benefit of necessary surgical measures, just as sane women would be, but further than that he did not advocate surgical interference.

Dr. Lawrence of Columbus, Ohio, said that the possibilities of an insane patient recovering from the mental disturbance were greater if all forms of irritation were removed. He did not know that removing some intra-abdominal or pelvic disorder would relieve the mental condition, but he did believe that putting such a patient in proper physical condition would help to bring about an improvement, if not a cure, of the mental condition.

Dr. Henry maintained that these pelvic disorders in women of unstable nervous organization were often the particular thing that upset the mind, and that cure of these conditions would prevent insanity, or, if the mental condi-

tion were already impaired, removal of the irritation would bring about a cure.

SECTION ON SURGERY AND ANATOMY.

Third Day—Thursday, June 7.

Radium in Surgical Work.—Dr. Robert Abbe of New York stated that epithelial cancers of the face are all curable by radium, especially when the tumor is situated in a locality where its removal by surgical means would necessitate a disfiguring operation. In his experience radium proved successful in cases where the Röntgen ray failed. The action of the radium resembles that of the Röntgen ray, but it differs specifically, curing some cases which resist the latter. It is applicable to the interior cavities of the nose and mouth which are inaccessible to the ray. Its sphere of usefulness is widening continually, as rapidly as its effects are being studied more carefully.

Primary Position in Bloodless Treatment of Congenital Hip Dislocation.—Dr. Frederick Mueller of Chicago claimed that the large percentage of subspinal positions after the Lorenz operation usually are due to a twisting and bending of the neck of the femur. If the head is replaced in its socket by the well-known maneuvers, it is forced out of its place again if the thigh is placed in the Lorenz primary position. This is due to the fact that the axis of the pocket-shaped recesses does not correspond to the position of the axis of the femur, head, and neck. Stable reposition requires that these axes correspond. Mueller places the femur in a neutral rectangular reduction so that the patella faces the frontal plane. This position is fixed by a cast which reaches down to the ankle or to the toes, if necessary. This position has given most beautiful results, even in cases in which the Lorenz operation failed. It can also be used advantageously for transforming subspinal positions into real anatomical positions.

Dr. Virgil P. Gibney of New York employed the bloodless reduction method in forty-three cases. Eight of these were anatomical cures; there were two functional cures; seventeen patients were improved; fourteen were unimproved; there was one doubtful case and one patient died.

Surgery of Peripheral Nerves.—Dr. J. B. Murphy of Chicago stated that all nerves of the lower motor neuron are capable of regeneration for a long period after division. This includes all the spinal and cranial motor nerves, all those nerves having a neurilemma. Nerves of the upper motor neuron are not capable of regeneration to functional activity. Motor nerves should all be restored to accurate apposition immediately after division, and also after paralysis from division, contusion or compression. Union and functional transmission is the uniform result. The interposition of foreign bodies, connective tissue, retard or even prevent nerve union. Regeneration and reestablishment of function is in proportion to the size of the trophic ganglion of the peripheric nerve. When the ganglion or trophic cell body is destroyed, axones are not regenerated.

Surgical Treatment of Facial Palsy and Brachial Birth Palsy.—Dr. Alfred S. Taylor of New York used the hypoglossal nerve in preference to the spinal accessory because of the more intimate anatomical and physiological relations of the muscle fields, the nuclei, and the cortical centers of the facial and hypoglossal nerves. Also in each case operated on the method of lateral implantation of the facial onto the hypoglossal trunk was used in preference to the transverse section of both nerves followed by end-to-end suture. He believes the results to be better. The return of power is very considerable. There is no mortality. Voluntary motion returns in every case to a greater or less extent, but it is very essential to follow systematic after-treatment for many months in order to obtain the best results. There is no time beyond which the operation is contraindicated so long as there is muscle tissue remaining; therefore from the beginning of the facial palsy, electricity, massage, and other means of maintaining the nutrition of the paralyzed muscle should be employed until such time as spontaneous cure occurs or operation is indicated. Inasmuch as no definite prognosis can be given, it is reasonable to wait one year for signs of spontaneous improvement before resorting to operation. In the brachial birth palsies early operation is indicated, that is, in from six to twelve months. The deformities should be prevented by massage both before and after operation.

Mr. Chas. Ballance of London, England, did the end-to-end anastomosis. On several occasions he had united the distal end of the hypoglossal nerve to the gustatory.

Dr. Harvey Cushing of Baltimore discussed, briefly, the histogenesis of nerve regeneration.

Dr. A. J. Ochsner of Chicago cited a case of ulnar nerve division following gunshot wound in which he bridged over a space of 7½ cm. by means of fine catgut strands, about twenty in number Within three years the patient possessed full control of the arm.

Dr. F. S. Lund of Boston operated on three patients according to Dr. Taylor's method with perfect results.

Ischemic Paralysis and Contracture of Volkmann.—Dr. Chas. A. Powers of Denver tabulated fifty-one cases collected from the literature and cited one personal case. The result (independent of treatment) was complete failure in ten cases; some improvement in fourteen, and a relatively good result in twenty-seven, implying more or less return of function. Of twenty-two cases treated by operation a good functional result seems to have been secured in the majority. Of the thirty non-operated cases good results were secured only in a minority and in several of these improvement was apparent only after years of observation. To save a muscle in its entirety the cause must be removed within five hours, for in about seven hours the rigidity supervenes, corresponding to rigor mortis. Regeneration cannot occur unless circulation is promptly reestablished. When the injury and its results are slight or moderate, time and proper treatment will accomplish much. Complete restoration of function is not known.

Treatment of Fractures of the Patella.—Dr. Jos. Ransohoff of Cincinnati presented a study of fifty-one cases with eighteen operations. He stated that fractures of the patella are often partial and subperiosteal and require no operative treatment, even if recognized. A master of aseptic surgery may operate in every case of patellar fracture where separation of the fragments can easily be recognized. Where the diastasis indicates the lateral involvement of the lateral expansions of the quadriceps, the indications for operation are plain, unless valid contraindications are present. The proper time for operation is the first week. The operation ordinarily indicated is the open operation with suture of the lateral tears and fixation of the fragments by some approved method. In old standing cases with very wide diastasis of the fragments, excision of the latter and suitable tendon plastic will probably give better results than bone suture. The knee joint should never be invaded by one who does occasional surgery. In the eighteen cases of this series operated on, the operation was performed twice on the second day, once on the third, twice on the fourth, and in the remaining cases before the fifteenth day. The only fatality occurred in a patient operated on on the seventy-ninth day. The average stay in the hospital of the early operations was thirty days; of the average non-operated cases it was sixty days. Of the late cases it was eighty-four days. Suture with silver wire was done five times, with kangaroo tendon or chromicized catgut nine times, and the tobacco-pouch suture was used in four cases. It did not appear that those sutured with silver wire did better than those sutured with animal suture. In one case it was necessary to remove the wire after the patient left the hospital. In two cases a considerable ankylosis remained.

Dr. Robert Weir of New York did not approve of opening the knee joint for treatment of fracture of the patella. If he were the patient he certainly would object to such a procedure.

Dr. Charles A. Powers of Denver favored operative interferencee because in his experience the results had been better than from nonoperative treatment.

Dr. A. T. Cabot of Boston stated that in the case of patients who can submit to a long course of treatment, he frequently carries out the expectant plan; but if the patient is one with whom time is an essential element, he prefers the operative treatment.

Diseases of the Urachus.—Dr. John F. Binnie of Kansas City reported a number of cases of this kind and discussed the occurrence and treatment of the various affections which may be found associated with a patent urachus.

Spontaneous Intracranial Hemorrhage.—Dr. Harvey Cushing of Baltimore reported three cases of focal epilepsy occurring in patients having the so-called "port-wine" marks in the ophthalmic distribution of the trigeminal nerve. Presumably a nevus of the dura existed in all these cases, and from this nevus one or more spontaneous hemorrhages, subdural, had taken place. Adhesions left after the absorption of the clot were doubtless the occasion of the motor discharges from the cortex. In one of the cases operation was attempted, but owing to extreme vascularity it was abandoned. In a second case a craniotomy, with separation of the adhesions, was successfully carried out. In the third case operation was considered inadvisable. Dr. Cushing stated that vascular nevi occurring on the face show a tendency to conform in outline with the distribution of one or more of the main trigeminal branches. These cutaneous nevi may be associated with some degree of hypertrophy of the deeper tissues of the face, with an enlargement of the eye, and finally with the presence of a corresponding nevoid condition of the dura mater. This dural nevus may lead to a spontaneous hemorrhage during infancy with consequences similar to those which follow the subdural hemorrhages occurring during the early months of life from other causes—epilepsy, spastic hemiplegia, or even amentia. The absorption of the clot may lead to corticodural adhesions, which in favorable cases could be separated with benefit to the epileptiform convulsions, provided measures such as carotid ligation are taken to prevent complications from too great a loss of blood during the operation.

Diagnosis and Treatment of Tuberculosis of the Kidney.—Dr. Arthur Dean Bevan of Chicago stated that the frequency of this condition is much greater than was supposed. In more than nine-tenths of the cases the lesion, for a time, is limited to one kidney. The second kidney, in long-standing cases, may become involved through an ascending infection from the bladder. The primary infection, in nearly all cases, occurs through the circulation. It is highly essential to make a diagnosis as soon as possible, before the second kidney is involved, and to institute the radical treatment of a nephrectomy at a time when the process is still limited to one kidney. Nephrotomy should not be done.

Dr. Van Buren Knott of Sioux City, Ia., considered the use of the cystoscope of the greatest assistance in arriving at an early diagnosis. He also condemned nephrotomy as a palliative operation. Nephrectomy should be performed in every case in which the disease can be located positively and it is confined to one kidney.

Dr. H. A. Kelly of Baltimore found that in man the disease may be primary in the generative organs, ascending from the testes; while in women it was primary in the kidney. He called attention to the frequency with which errors in diagnosis may be made by placing too great reliance on what are now considered positive symptoms. The wrong kidney may be excised or treated. This should be avoided by careful study of the history and by carefully weighing all the findings. Nephrotomy may be necessary as a temporary means to relieve the patient, but nephrectomy should follow. However, in some instances it may be imperative to resort to nephrotomy, when the other kidney had been previously removed for tuberculosis. One patient so operated on was in perfect health four years after the operation.

Dr. Willy Meyer of New York stated that the most important symptom was frequent urination, at night as well as in the daytime. The pain may be misleading. It may be absent or it may be referred to the opposite side. Ulceration of the ureteral orifice is also an important sign and should not be disregarded. Nephrectomy should be done as early as possible and this should be followed by proper hygienic treatment—not preceded by it, as is often done.

Dr. Jos. Ransohoff of Cincinati did not believe that the infection ever was an ascending one because the tubercle bacillus is nonmotile. He did not favor nephrotomy as a final operation.

Dr. L. L. MacArthur of Chicago believed that in cases of mixed infection it is better to drain the affected kidney for four or five weeks, removing the septic products, before attempting more drastic measures. The final results will be better.

Surgical Aspects of Congenital Cystic Kidney.—Dr. F. B. Lund of Boston stated that it was important to recognize the true condition in these cases because usually both kidneys are affected. Nephrectomy often results in causing death from uremia. The best treatment in the case of large cystic kidneys causing symptoms is incision of the large cysts and packing with gauze, also fixation by suture, if movable. This condition is one of great importance to the obstetrician and to the surgeon. It frequently runs its course undeterred until the secondary renal or arteriosclerotic changes result in death. Surgical interest results from the fact that the tumor, because of its size, frequently causes dragging and pain, and often immobility of the kidney. When cut down on it may easily be mistaken for carcinoma or adenoma of the kidney.

Treatment of Bone Cavities.—Dr. J. E. Moore of Minneapolis discussed the treatment of bone cavities by filling it with a material similar to the Mosetig bone plug. He found the following the most satisfactory of his experience: Spermaceti, 8 parts; olive oil, 2 parts; iodine, 1 per cent. The spermaceti is melted at a low heat on a water bath and the olive oil is added. The iodine is dissolved in the liquid, which is stirred until it congeals. Heat must not be used after the iodine is added. The mass is solid at the body temperature; melts at 108 F. and is antiseptic without being irritating. The iodine was considered preferable to iodoform because it was soluble, inexpensive, and more actively antiseptic than iodoform.

Uterine Fibroids Associated with Gallstones.—Dr. A. Vander Veer of Albany reported four cases of uterine fibroid in which there was a history of biliary colic, and two in which the history was not clear. He advised that once the peritoneal cavity had been invaded the appendix as well as the gall-bladder be inspected carefully and operative intervention resorted to if necessary.

Technique of Operations on the Head and Neck.—Dr. George W. Crile of Cleveland stated that in operations for malignant diseases the plan of the operation should be determined by the necessities of entire removal rather than a set technique. Principles, not rules, should govern the technique. The control of the blood pressure, both local and general, are of paramount importance. The principal sources of danger are mucopulmonary infection, hemorrhage, and shock. The blood supply of the brain should, as far as possible, be conserved. Crile places the patient in a tightly fitting sack which causes an anemia of the upper part of the body. The application of a principle of dissection as thorough as that generally employed in operations for cancer of the breast, having due regard for all the lymphatics, both the superficial and the deep groups, should give as good results in this region as in the former. As a rule, operators do not consider the lymphatics sufficiently when operating on the head and neck region.

Dr. R. H. M. Dawbarn of New York referred to his work of ligating the external carotid—the starvation operation. He said that by constricting the limbs tight enough to accumulate the blood in the extremities, it is not necessary to resort to the use of Dr. Crile's rubber suit or the slanting

posture described. Such operations as resection of the jaw and removal of adenoids may in this manner be rendered bloodless. If, when the constriction is removed, hemorrhage ensues, the application of gauze wrung out of hot water at a temperature of 212 F. will immediately check the bleeding.

Dislocation of the Outer End of the Clavicle.—Dr. Charles L. Scudder of Boston reported two cases of complete dislocation of the clavicle in which operation was necessary because of the irreducibility of the dislocation and the failure to maintain reduction once it was affected. About six weeks after the accident a suture of the acromioclavicular joint was made, using linen and catgut in one case and aluminum bronze wire in the other. The suture was passed through the acromion process and outer side of the clavicle, and another might be passed through the clavicle or fibrous tissue of the joint and through the coracoacromion ligament. The result was a promptly occurring and a permanent one.

Surgical Treatment of Congenital Hydrocephalus.—Dr. J. Shelton Horseley reported a case of large hydrocephalus, congenital, with a large meningocele at the base of the skull. The meningocele was removed and the patient recovered, but the hydrocephalus continued to grow. Various operative procedures were adopted, but the only one that proved satisfactory was continuous drainage by the direct open method through a malleable silver tube. The patient finally died from enterocolitis.

Osteoplastic Resection of the Costal Arch in Order to Reach the Vault of the Diaphragm.—Dr. Willy Meyer of New York illustrated his paper fully by means of drawings and pointed out the advisability of the procedure advocated by him in the treatment of conditions, such as abscess, etc., involving the tissues immediately under the diaphragm.

Capillarity in Intestinal Suturing.—Dr. F. Gregory Connell of Salida, Colo., presented the results of an experimental study aiming to show that the danger of peritoneal infection by capillary action of the suture material had been greatly exaggerated. Capillarity in this connection was generally understood to mean the seepage or extending of a fluid along the suture beyond that portion which was in direct contact with the fluid. The extent of the capillary action depended on various modifying conditions, the most important of which was an inhibitory action of the mucous lining and contents of the intestinal canal.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

Stated Meeting, Held March 20, 1906.

Dr. Warren Coleman in the Chair.

Specimen of Congenital Defect of the Interauricular Septum of the Heart.—Dr. A. M. Pappenheimer presented this specimen, which was removed from a child of four months who was brought to Bellevue Hospital in a dying condition. There were no cardiac murmurs, clubbing of the fingers, or other indications of cardiac involvement. There was a papular rash, which pointed to a possible specific history. The heart was moderately enlarged, the hypertrophy affecting the right auricle and conus arteriosus. In place of a normal septum between the auricles there was a defect filled in by a curtain made up of fine fibrillary lattice work. Sketches were presented showing the conditions, which were interesting, not only from their rarity, but from a developmental point of view.

Dr. Alfred Meyer said the specimen was interesting from a physico-diagnostic point of view. So far as auscultation was concerned there had been no diagnosis made of the defect, probably because the child was in a dying condition when brought to the hospital. This was in keeping with organic disease as it occurred in the adult; shortly before death even extensive disease of one or more valves gave nothing upon auscultation. He asked how long the child lived after it came under observation.

Dr. Pappenheimer replied that it lived only two hours. There was a patent foramen ovale, a condition fairly common without giving signs of distress just prior to death.

A Case of Yellow Fever.—Dr. Harlow Brooks related the case of a powerful Italian who presented himself at a dispensary after three days' indisposition, followed by three days' severe illness. He was deeply jaundiced, had a temperature of 104.5°, and a rapid, strong pulse. He complained of pain in the back of the head and neck and of marked nausea. He constantly vomited greenish brown material, and could retain neither food nor drink. He was sent to a hospital, and by the time he had reached his destination he was in practically a moribund condition. His temperature had fallen to 98°, and the pulse remained weak and rapid, and the heart sounds were muffled. He claimed to have lived in New York for four weeks before this time, but investigation showed that he had no doubt overstated the time, and had fled from New Orleans on account of the yellow fever epidemic. He had evaded quarantine in some manner which could not be traced. As these facts could not be obtained at the time, he was thought to be suffering from a severe form of malaria. The blood failed to show the malarial plasmodia. An ambulance surgeon who was a recent graduate insisted that the case was one of yellow fever. The patient died before morning. At the autopsy very pronounced olive green pigmentation of all the tissues of the body, evidences of hemolysis, microscopic hemorrhages in the skin and mucosa, and a fatty and dilated heart were found. The spleen was greatly enlarged, 23 cm. in length, 9.5 cm. in breadth, and 3.5 cm. in thickness. The tissue was firm and deep olive green in color. The liver was enlarged, soft, and congested. There was general edema of all tissues, and the lymph nodes were universally enlarged and congested. The case was diagnosed as probably one of extreme anemia following severe and long-standing malaria. The microscopic examination showed nothing of importance save a very pronounced pigmentation, except in the liver, where extensive necrosis of the centrally situated cells of the lobules was found; about the periphery of the lobules many liver cells showed karyokinetic figures. The necrosed cells showed alterations simulating acute yellow atrophy, Wei's disease, or yellow fever. Taking the negative blood findings, with the history and clinical and anatomical characteristics presented, the diagnosis of yellow fever seemed justified. On account of the newspaper notoriety it was decided not to put the case on record at that time, but he wished now to put the case on record, as he believed it to be the only case that had developed in New York City in some years. It also illustrated the great possibilities which still existed in our quarantine system by means of which cases direct from an infected district might gain access to our thickly populated tenement districts. The case demonstrated as well that eternal vigilance must be exercised by those in charge of hospital and dispensary work in New York City as there was practically no disease that might not at any time present itself.

The Fate of the Typhoid Bacilli in the Organism.—Dr. B. H. Buxton gave an account of his experiments in which he injected normal rabbits intraperitoneally with typhoid bacilli with the object of determining the fate of the bacilli in the organism. For purposes of injection he used a culture of moderate virulence which had been kept on artificial media for four years. Its virulence might be considered constant. He used agar tubes and injected one-half of a twenty-hour-old culture. Repeated tests by plating showed that the dose might be taken as of the order of 4,000 million bacilli. He followed Bail's method of bleeding the rabbit from the carotid and then removing the organs. The spleen was taken as the unit, and a piece of

the liver the same size as the spleen was taken. These pieces were rubbed through fine wire gauze with 15 c.c. of salt solution, and one c.c. of this pulp was plated out in agar and the colonies counted after twenty-four hours. Other organs were tested, but he confined his present report to the liver and spleen. From the number of colonies on the plates a rough estimate of the total number in the organ could be made by multiplying the count for the spleen by 15, and that for the liver by about 1,500. Immediately after bleeding and before opening the abdomen the peritoneal cavity was washed out with 400 c.c. salt solution. Portions of the wash water were plated out and a rough estimate made of the number of bacilli remaining alive in the abdominal cavity. The rabbits were killed at intervals of two, four, and six hours after intraperitoneal injection. The numbers found varied very greatly, but one fact stood out, namely, that the bacilli were always more numerous in the liver than in the spleen, not only absolutely, but relatively. If the bacilli were numerous in the liver they were also numerous in the peritoneal cavity. In two cases in which there were over a thousand found in the liver there were several million alive in the peritoneal cavity; two cases with about 100 each on the liver plates showed about half a million alive in the peritoneal cavity; and two cases in which there were few or none in the liver showed few or none in the cavity. The results when the rabbits were killed at the end of four and six hours were very similar, though on the whole the number of bacilli appeared to increase. After sixteen hours the number of bacilli in the liver had decreased much more than in the spleen, and the relative amounts were about the same in the two organs. After twenty-four and forty-eight hours there were usually still a goodly number in the spleen, but scarcely any in the liver. After inoculation one had not the least idea what would happen. Sometimes the rabbit seemed hardly affected. A rabbit killed four or six hours after inoculation might have killed practically all the bacilli or might be swarming with them. As a rule, however, the rabbits got very sick about two hours after inoculation. Such a rabbit might die after three or four hours, might live several hours longer, and then die or recover. The size of the rabbit seemed to have little to do with the result. It was generally accepted that typhotoxin was an endotoxin, which was liberated only upon the death of the bacilli, and that if an animal died three or four hours after inoculation it was because it had killed so many bacilli that the toxins liberated had killed the animal. He had had rabbits die at the end of three or four hours and found scarcely any bacilli, and again he had found them literally swarming with bacilli. When death occurred so quickly it was impossible to suppose there had been enormous destruction and at the same time an enormous increase in the number of those left alive. Death under these conditions might be accounted for by the fact that the bacilli flood the organism very rapidly, and there might be destruction of a certain number at some vital point as a nerve center. If the destruction took place in the peritoneal cavity a very much larger dose of the endotoxin would be required to cause death. Experiments were made at one hour-, thirty-minute and fifteen-minute intervals with similar results. The organs might be already filled with bacilli. Finally the whole operation was conducted as quickly as possible, the entire time being only ten minutes from inoculation to the stoppage of circulation, and the result was that some were found flooded with bacilli and some not. One salient feature was that what went on in the peritoneal cavity was usually only a part, and a small part, perhaps, of the whole process by which the animal protected itself from infection.

The Albumin Bodies in the Urine; the Recognition of Serum Albumin and Serum Globulin.—Dr. THOMAS W. HASTINGS read this paper. (See page 13.)

Dr. E. E. Smith said that under the heading of albuminous substances Dr. Hastings had included some things that he had been accustomed to regard as proteid in nature, as, for instance, hematoporphyrin. He asked Dr. Hastings if he included in this list the mucin bodies. Dr. Smith said he had done considerable work in the chemistry of mucous conditions, and he was rather skeptical regarding the presence of these mucous-like bodies in the urine at all. In the literature he had only found one statement that anyone had succeeded in recognizing a substance as mucin in the urine. Dr. Smith's routine procedure in examining urines was to throw down any proteid material which might be a foreign substance, and then to apply cold nitric acid, looking for the contact test after adding to the urine one-fourth its volume of a saturated salt solution. If urates were present they would be recognized by their disappearance on heating in the contact test. He relied upon this more for the qualitative than for quantitative purposes.

Dr. HARLOW BROOKS said that he felt rather skeptical regarding the urinary findings. He believed that men were too careless in the examination of the urine. Where albumin should have been present he had often missed it through defective or careless technique. He said he was glad that Dr. Hastings had brought up this subject, and thought that all would appreciate it.

Dr. Hastings said that hematoporphyrin was a derivative of a proteid, formed by the breaking down of the blood pigment. If one went into a separation of all these bodies the task would be an endless one. With regard to the mucin bodies physiological chemists recognized the work being done and the difference between mucin bodies and nucleo bodies. Mucin contained no phosphorus. The use of nitric acid and saturated salt solution he considered one of the best tests.

Organic Heart Disease and Immunity from Phthisis Pulmonalis.—Dr. BOND STOW presented this paper. He said that whether organic heart disease did or did not grant immunity from phthisis pulmonalis depended upon the presence or absence of a coexisting long-standing passive hyperemia in the pulmonary circulation. In view of the anatomical relations of the heart and the lungs the heart seemed more intimately associated in a causal relation to certain diseases of the lungs than any other organ. Even a slight disturbance in the heart's action exerted a direct influence upon the pulmonary circulation. Long-standing circulatory disturbances left their indelible stamp upon the pulmonary tissues. Where there was a hindrance to the passage of blood into the pulmonary arteries we had pulmonary stenosis; quite a different state resulted when there was a free entrance into the pulmonary arteries with a retarded exit from the pulmonary veins through the left auricle as appertained in a well-marked case of mitral stenosis. These two conditions were diametrically opposed to each other, and statistics proved that the one just as surely predisposed to tuberculosis as that the other granted immunity. The question of immunity seemed to resolve itself into the amount of blood within the pulmonary tissues. At the present day, when autopsies were carefully performed, statistics showed that in 83.3 per cent. of those having stenosis of the pulmonary valve, tuberculosis of the lungs followed. What was true of pulmonary stenosis was almost as much so of that rare condition, tricuspid stenosis. He concluded as follows: 1. Organic valvular diseases of the right side of the heart that produced pulmonary anemia afforded conditions favorable for the ready growth of the tubercle bacillus, and were, as a fact, most frequently associated with phthisis pulmonalis. 2. Organic valvular diseases of the left side of the heart, when accompanied by well-marked secondary changes of hypertrophy and dilatation, producing long-standing passive hyperemia of the lungs, were very rarely followed by tuberculosis of the lungs and not infrequently effected an extinction of a previously existing tuberculosis. 3. The exceptional cases that did arise must be accounted for by certain qualitative and quantitative changes in the bactericidal properties of the blood reducing its immunizing powers. Nature clearly pointed the way to the treatment

of incipient tuberculosis in two instances, chronic emphysema and those valvular heart lesions that produced long-standing pulmonary congestion. In both these instances the autopsy frequently revealed quite extensive tuberculous processes that had become entirely extinct. On the other hand pathologists and clinicians agreed that tuberculosis rarely followed these two conditions. The underlying pathological condition produced by these two affections was a constant passive congestion of the lungs. This meant that there should be collected and kept in the lungs an increase of those agents of the blood that were antagonistic to the growth of bacterial life. This suggested in the treatment of incipient tuberculosis physical exercise in the open air several times a day, sufficient to produce heavy congestion of the lungs; not gentle walking or riding in a carriage, but running to the point that the congested lesser circulation interfered with the free action of the right ventricle and forced temporary rest. Naturally one must be governed by the conditions in each individual case as to the amount and character of the exercise prescribed. To this exercise should be added climatic conditions high in oxygen, and therefore comparatively free from green life and plenty of food, such as experience taught would best build up nature's defenses against microbial life, namely, the bactericidal properties of the blood. The dangers of overexertion in advanced cases were referred to and the risk that was assumed in incipient cases. He cited a number of cases, including gross and microscopical specimens of the same, illustrating the effect of organic heart disease upon the tuberculous process in the lungs.

Dr. Egbert Le Fevre took a positive exception to Dr. Stow's therapeutic deductions for the treatment of incipient tuberculosis, and said that his method of producing passive congestion of the lungs was radically different from Nature's way when there was an obstruction at the mitral orifice. In cases of incipient tuberculosis, when the patient exercised, there was a congestion of the lungs but *not* a passive congestion as occurred in organic mitral stenosis. In tuberculosis the nearer we came to physical rest of the part, the better the case would progress. Such exercises as advised by Dr. Stow were wrong.

Dr. C. N. B. Camac said that he had looked over the records at the Cornell dispensary and found that out of 6,000 general cases about 350 were tuberculous. In that lot of 350 there were no cases of mitral or aortic murmurs, but there were a number of cases in which a murmur was heard over the pulmonic area, mostly systolic. Occasionally a diastolic murmur would be heard, and he had seen three such cases associated with pulmonary congestion.

Dr. Alfred Meyer said that the relation of pulmonary tuberculosis to valvular lesions of the left side of the heart and the frequency of their coexistence had long been and still continued to be a moot question. He said that Dr. Stow had gathered some statistics, personal and otherwise, showing that they tended to exclude each other, and that the cardiac lesion under certain conditions even aided the reparative processes in a preexisting pulmonary tuberculosis. This in the main was the view advanced many years ago by Rokitansky. Other statistics, however, had been published which seemed to indicate a rather frequent coexistence of these two diseases, or at least to disprove the old view of their excluding each other. On one point there seemed to be general agreement: The frequent coexistence of pulmonary tuberculosis and stenosis of the pulmonary valve, as much as 80 per cent. of the latter disease showing tuberculous changes in the lungs. There was one point of diagnostic interest which should be referred to: How should an area of pulmonary dullness and bronchovesicular breathing be interpreted when occurring in a patient with mitral stenosis, or stenosis and insufficiency, if he had had hemoptysis? If one had the bacillary proof, well and good; but if one had not, there was in these cases always at least a possibility that the physical signs in the lung were due to pulmonary infarcts.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the City, for the week ending June 30, 1906.

	Cases	Deaths
Tuberculosis Pulmonalis	362	180
Diphtheria	242	30
Measles	440	12
Scarlet Fever	110	9
Smallpox	3	—
Varicella	59	—
Typhoid Fever	30	14
Whooping Cough	39	4
Cerebrospinal Meningitis	29	16
Malarial Fever	.....	.....
Totals	1,323	265

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon General, Public Health and Marine Hospital Service for the week ending June 29, 1906.

SMALLPOX—UNITED STATES.

		CASES.	DEATHS.
California, Los Angeles	June 9–16	1	.
Florida, General	June 16–23	4	.
Jacksonville	June 16–23	2	.
Illinois, Galesburg	June 16–23	4	.
Kansas, Topeka	June 13–20	1	.
Kentucky, Covington	June 16–23	1	.
Louisiana, New Orleans	June 16–23	16	.
Missouri, St. Louis	June 16–23	1	.
New York, Findlay Lake	June 22	1	.
New York	June 16–23	4	.
North Carolina, Beaufort	June 22	2	.
Ohio, Cincinnati	June 15–22	3	.
Tennessee, Nashville	June 16–23	2	.
Wisconsin, Appleton	June 16–23	1	.
Milwaukee	June 16–23	2	.

SMALLPOX—INSULAR.

Philippine Islands, Manila	May 5–12	1	.

SMALLPOX—FOREIGN.

Africa, Cape Town	May 12–19	2	.
Brazil, Rio de Janeiro	May 13–27	3	.
Canada, Toronto	June 2–16	10	.
Winnipeg	June 9–16	1	.
Chile, Antofagasta	May 26	9	.
Iquique	May 12–19		Present.
Talcahuana, vicinity	May 19–26		Present.
China, Hongkong	May 12–19	2	1
Shanghai	May 19–26		1
France, Marseilles	May 1–31		1
Paris	May 26–June 2	6	.
Germany, Bremen	May 26–June 2		1
Great Britain, Hull	May 26–June 2	2	.
Liverpool	June 2–9	2	.
Greece, Athens	May 28–June 4		2
India, Bombay	May 22–29		5
Calcutta	May 12–19		44
Karachi	May 20–27	19	4
Madras	May 19–26		4
Rangoon	May 12–19		17
Italy, General	May 31–June 7	18	.
Messina	May 26–June 2		1
Netherlands, The, Groningen	Apr. 15–30	5	.
Russia, Moscow	May 26–June 2	4	2
Odessa	May 26–June 2	14	.
St. Petersburg	May 12–June 2	27	8
Spain, Cadiz	May 1–31		1
Turkey, Constantinople	June 3–10		1
Switzerland, Zurich	May 26–June 2	1	.

YELLOW FEVER—UNITED STATES.

Louisiana, Mississippi River Quarantine	June 23	1	Imported from Habana on S. S. *Holstein.*

YELLOW FEVER—FOREIGN.

Brazil, Rio de Janeiro	May 13–27	1	.
Honduras, Choloma	June 2–9		Present.
Puminta	June 2–9		Present.
San Pedro	June 2–9		Present.
Mexico, Merida	June 1–16	2	2

CHOLERA—INSULA

Philippine Islands, Manila	May 10–17	6	6

CHOLERA—FOREIGN.

India, Bombay	May 22–29		22
Calcutta	May 12–19		37
Rangoon	May 12–19		2

PLAGUE

Brazil, Rio de Janeiro	May 13–27	1	.
Chile, Tacna	May 26		Present.
China, Hongkong	May 12–19	90	83
Egypt, Alexandria	June 4–5	1	1
Keneh	June 2–7	6	4
Minich	June 1–7	4	4
India, General	May 5–12	13,207	11,414
Bombay	May 22–29		317
Calcutta	May 12–19		42
Karachi	May 20–27	101	96
Rangoon	May 16–19		40
Japan, Hiroshima-Ken	June 5		Present.
Kobe	June 5		Present.
Yokohama	June 5	1	On S. S. *Siberia.*
Peru, Mollendo	May 15–23	1	.

A NEW METHOD OF INCISION FOR REMOVAL OF THE BREAST.*

BY CARL BECK, M.D.,

NEW YORK.

PROFESSOR OF SURGERY IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL, VISITING SURGEON TO THE ST. MARK'S AND THE GERMAN POLIKLINIK.

EXTENSIVE removal of the mamma creates a large defect, which can be covered only by an additional plastic operation. Some surgeons prefer skin grafting and others allow the gap to fill up by granulation.

It is a common feature of all the valuable methods of amputatio mammæ that the operation is begun with an elliptical or oval incision around the breast. To this, as a rule, further incisions are added in different directions.

The general tendency is to cover the large wound produced by the extensive removal of mamma plus

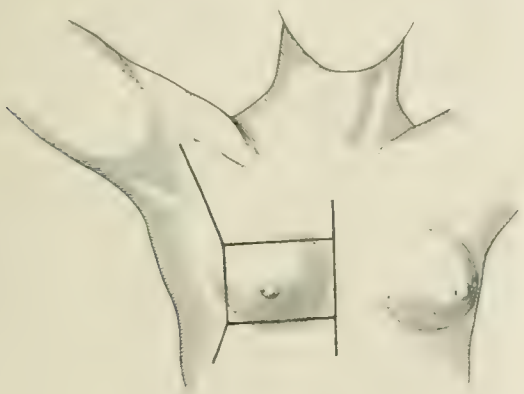

FIG. 1.—Lines of Incision.

surrounding tissue, by drawing in skin tissue from above and from the side. In the great majority of cases tension is caused by the more or less forcible apposition of the flaps. This is frequently followed by separation of the sutures as well as by irregular cicatrization, the latter itself being a provoking moment for early recurrence of a malignat neoplasm. Lateral elongation of the elliptical incision somewhat diminishes the tension. For that purpose I have devised the formation of a lateral flap, which has done me good service in a few cases (*Clinical Recorder*, October, 1896).

Below the mamma there is an abundance of integumental material. This fact, which might be utilized for covering a considerable defect, has, to my knowledge, not been appreciated—at least not in a methodical manner, although the idea is rather obvious.

In carrying out these considerations I began by giving my incision line around the breast the form of a rectangle (Fig. 1). The interior line of the rectangle is continued on both ends to the extent of about three inches. The same is done with the lower end of the external side, while the upper exterior end is extended along the outer margin of the pectoralis major muscle up to its humeral insertion.

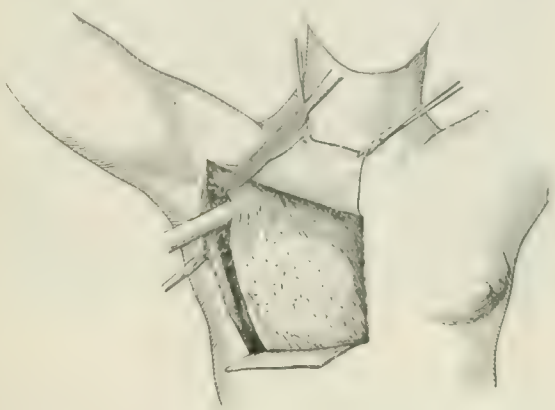

FIG. 2.—Flap reflected and pectoralis major muscle dissected up at its humeral insertion.

The axilla itself is not touched, in order to avoid cicatrization in the axilla, which is apt to produce edema brachii.

After the rectangle, including the whole breast, is excised the upper skin flap is formed and reflected. Thus the area of operation is fully exposed. Whether the fascia and the upper layer of the pectoralis major muscle only are removed, or whether, preferably, the radical operation is performed, the

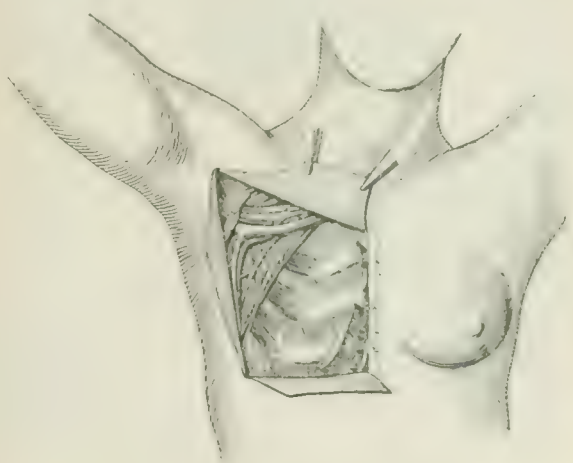

FIG. 3—Pectoralis major muscle removed and axillary vessels isolated.

principle of access remains the same. I do not dispute the propriety of the less radical method in selected cases, especially when the carcinoma is of recent origin and very small; but even in this event I would insist upon the complete removal of the outer margin of the pectoralis major muscle, be-

*Demonstrated before the New York German Medical Society, April 2, 1906.

cause it generally covers one or more infiltrated glands, from which lymphatics lead to the axilla. If they are overlooked a speedy recurrence may be expected.

In general I am in favor of the most radical procedures, especially as advocated by Halsted. They

Fig. 4.—Immediately after operation.

would be severing of the pectoralis major muscle from its clavicular and costal attachments as well as from its humeral insertion (Fig. 2), removing the pectoralis minor muscle, furthermore dissecting away the axillary contents, so that the vessels are completely isolated, also cleaning the posterior wall of the axilla after spreading out the tissues on the latissimus dorsi, subscapularis, and teres major muscles (Fig. 3).

Now the lower flap is lifted up and reflected. By gently drawing the upper flap downward and the lower flap upward one can feel, without tension, whether apposition can be attained. If there be any

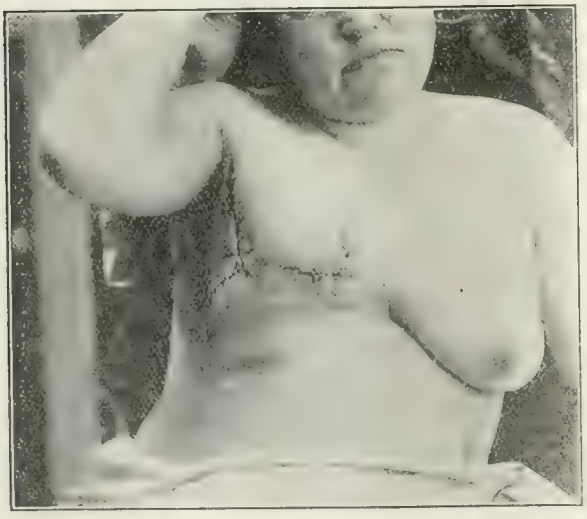

Fig. 5.—One week after operation.

tension, the lower flap is made longer by extending the incision line on both sides. The straight shape of the flaps greatly facilitates exact coaptation. (See Fig. 4.)

The wound margins are united by thin catgut. Both ends of the cross line are strengthened by the introduction of the marginal relaxation suture, consisting of silk. Into the upper end of the oblique incision line a small wick is inserted in order to drain the axilla for a day or two. As soon as the sutures are removed Roentgen treatment is begun.

The patient whom I present to-day is a woman of forty years, who had several attacks of rheumatism, and is now suffering from a slight insufficiency of the mitral valve. She is well nourished and appears to be well otherwise. Six months ago she noted an induration below her right nipple, to which she paid no attention, until her family physician insisted upon an operation. She submitted hesitatingly because she felt well and suffered no pain.

The radical operation, after the principles described, was carried out without any difficulty. The loss of blood was moderate. In spite of the vitium cordis the ether anesthesia was fair. Recovery was uninterrupted, the patient leaving the hospital two weeks after the operation. (See Figs. 4 and 5.)

To-day, six weeks afterward, the area of operation is completely movable, the cicatrices showing no adherence whatever. As far as the cosmetic result is concerned I dare say that it distinguishes itself favorably from any of my previous ones.

THE CONTAGIOUSNESS OF GUMMA.

By CHARLES MALLORY WILLIAMS, A.B., Ph.B., M.D.,

NEW YORK.

CLINICAL ASSISTANT AND CLINICAL REGISTRAR, NEW YORK SKIN AND CANCER HOSPITAL.

Of the many questions that arise in the practice of medicine, one of the most important, as well as the most difficult, concerns the contagiousness of the disease or of certain of its manifestations—the danger to the community arising from the presence in it of the invalid. How soon, for instance, is it safe to raise the quarantine from a case of diphtheria? Must one wait till the diphtheria bacilli no longer appear in the secretions? Again, how real is the danger of contagion in pneumonia? When do the exanthemata first become dangerous and when does the danger cease? And from which of their lesions is infection to be feared? Leprosy has been a riddle for years, and though we believe that the organism causing it has been found, can we say how it is carried? So in syphilis, though the infecting power of certain of its products is established, with regard to others we are still uncertain, and it is the purpose of this paper to collect and to discuss the evidence for and against the contagiousness of a single lesion, the gumma. The proper presentation of the case, however, will involve reference to many closely allied issues, such as the duration of the period of contagion by secondary symptoms, and the duration of the possibility of transmission by inheritance.

Considering the known virulence of the primary lesion and of many of the secondary, it would be reasonable to expect later and even severer manifestations to be equally contagious. Experience has shown, however, that the vast majority of cases owe their origin to sufferers in the early stages, and that repeated exposures to tertiary lesions have not been followed by infection. Hence arose the generalization that tertiary lesions are not contagious. But is not this generalization founded on insufficient data? Exposure to a tertiary lesion does not always result in infection, it is true, but this does not prove that such lesions are incapable of propagating the disease; for exposure even to the virulent primary and secondary manifestations is often without result. Think for a moment of the enormous number of

secondary lesions of the skin and of the mouth, all capable of transmitting the disease, and of the comparative rarity of infection from these lesions, for the percentage of cases of such origin is certainly not greater than that of extra-genital chancre, which is estimated by Fournier[25] at 7 to 10 per cent. If the innumerable virulent extra-genital secondary manifestations produce so few new cases, is it any wonder that the admittedly less active tertiary lesions produce still fewer? There are many instances recorded in medical literature of escape from almost certain infection. For instance Fournier[22] reports that he noted repeatedly that when several men had intercourse with one woman at the same time, some were infected by her, and others escaped. He quotes Pouch as having seen a case where a man contracted syphilis while his wife was "en couche," and before the chancre was healed had intercourse with her nearly every day—yet the wife was not infected. Barthelemy, again, reports the case of an infant, the child of healthy parents, who for a month suckled a breast on which was a typical chancre, which later was followed by secondaries—yet the child remained well. We must confess then that the records of exposure to tertiary manifestations, without infection resulting, are of little or no weight in deciding the question before us.

Some explanation is necessary, however, of the extreme rarity of records of such transmissions. I say records, because the idea of the non-contagious nature of gummata is so firmly established in the minds of the profession that cases in conflict with it are never looked for, and when they force themselves into view they are often dismissed with the mental comment that the infection must have come from some other unknown source, the physician preferring to invoke chance or marital infidelity rather than give up his theory. But, after making all allowance for these omissions, the cases probably are very scarce, and for several reasons.

In the first place, tertiary lesions are much rarer than secondary. Out of 11,639 patients suffering from syphilis in Neumann's[46] clinic, at Vienna, only 520, less than 4½ per cent., had tertiary lesions; and when we consider that tertiary lesions are often single, while secondary lesions are usually multiple, the difference in frequency of occurrence of the two types must be many times greater than the above figures indicate. Some other authors give higher percentages of tertiary patients, but I think it is never estimated at more than 18 per cent. of the total number of syphilitics, and 8 to 12 per cent. is a more common figure.

The site of tertiary lesions also is not generally favorable to the spread of the disease. In spite of the wide distribution of secondary symptoms on various parts of the body, and their known virulence, they seldom lead to contagion, except when situated on the genitals, which seem to furnish the conditions most favorable to infection. This favorable region, so often, if not universally, involved in the early periods, is much less often the seat of tertiary lesions. So in Neumann's[46] clinic of 277 men with tertiary syphilis, only one had any eruption on the genitals—a gumma of the penis; only one out of 5,702 males with syphilis. In women the involvement of the genitals in tertiary syphilis was much greater, yet even here, out of 243, only 37 had gummatous affections of the genitals, anus, rectum, or urethra—only 37 out of 5,991 syphilitic women. Of the whole 520, men and women, in only 38, about 7.3 per cent., were there lesions on the genitals. Fournier's[25] statistics of 4,400 patients showing 5,762 tertiary lesions contain only 271 instances (about 6.1 per cent.) of involvement of the genitals. These figures give one a vary fair idea of the rarity of such localization, in comparison with the total number of syphilitic subjects. Now, most of the instances of transmission of syphilis late in the disease have occurred in married life, and usually it is the man who is the source of the infection, and as the above figures show, it is the man who is the least likely to have lesions on his genitals. A woman who has had syphilis for several years is not so apt to have the opportunity to communicate her disease—and especially in marriage, where confrontation may best be obtained, and where other sources of infection may most surely be excluded.

A third factor which is apt to interfere with the opportunity for contagion from a gumma is the gross appearance of the latter. It is a deformity sufficiently obvious to be noticed by almost anyone, its appearance is menacing, and it usuall drives its victim to medical treatment, while a small eroded papule of the glans or of the sulcus is such an apparently insignificant affair that it may be, and indeed often is, entirely overlooked.

A fourth factor is the age at which tertiary lesions appear. Primary syphilis is essentially a disease of youth, and after the twenty-fourth year the chances of contagion—and also of infecting others—grow steadily less.[26] The interval of two or more years after which the gumma follows the chancre, will usually mean a greatly diminished number of occasions for contaminating others.

The considerable lapse of time between the original infection and the appearance of tertiary lesions is often invoked to explain the apparent lack of contagiousness of the latter, and it is the common belief at the present time that, with the passing of the years, the virus becomes more and more feeble, and finally dies out of the system. Doubtless this is true in many, even in most cases, especially when thoroughly treated. In a patient who shows no symptoms, secondary, tertiary or parasyphilitic, from the second or third year of his disease up to his death from some other cause, it may safely be assumed that the taint has been extinguished. But it is hard to see why the doctrine of the attenuation of the virus should be extended from such cases to those others in whom typical secondary symptoms appear five, ten, twenty, even thirty years after the infection. It seems to me utterly unreasonable to state that because the contagion has lost its virulence in a case that is cured, either by treatment or by the *vis medicatrix naturæ* (which is only a more accurate way of saying by the lapse of time), therefore it has lost its virulence in a case which still shows characteristic symptoms. The occurrence of these symptoms many years after the infection is an established fact. Fournier[25] states that out of 19,000 cases of syphilis in 1906, over 5 per cent., symptoms of secondary type were seen after the third year, and in 501 after the sixth year. These instances of late recurrence,[1 24 36 48 59] though somewhat rare, are more common than is generally supposed, and they are just as dangerous in the tenth year after the infection as in the second. Thus Fournier says: "Now are they contagious, in spite of their appearance at a period more or less beyond the ordinary limits of the secondary period? Most assuredly yes, or at least they may be so." Neumann[45] states that contagiousness lasts as long as the secondary symptoms. Neisser[42] is only a little less explicit; he says: "Is a syphilitic with tertiary lesions to be considered infectious or not? Only the duration of the disease and the energy and frequency of treatment are guides; except in the case of late secondary

symptoms"—thus agreeing that the latter are always contagious. Feulard[13] reported at the Third International Congress of Dermatology at London, 1896, 18 cases of contagion from late secondary lesions, at periods ranging from the fifth to the eighteenth year of the disease, and Tarassevitch[56] has added 27 to the number. Many others have been reported since, of which the following may be taken as examples:

Case I.—Reported by Jacob Halpern (*Archiv für Dermatologie und Syphilis,* 1894. Vol. 28, p. 67).

A man 35 years old developed a chancre of the penis, which was not followed by any secondary eruption; but three months later his wife had general syphilis. He had had intercourse also with another woman, Mrs. Y., 33 years old, who had been married ten years. Three years after her marriage Mrs. Y. had borne a full term child, who died soon. In the sixth and again in the seventh year of her marriage she bore a child, who in its third week developed an eruption that was cured by gray salve. The younger child died at 2 years of age of convulsions; the older is anemic, but otherwise well. Mrs. Y. has a papular syphilide on the right scapular region, and recurrent mucous papules on the portio vaginalis uteri.

Case II.—Reported by Filarétopuolo (*La Médecine Orientale,* Paris, 1900, p. 121).

The patient, a hard smoker and drinker, was treated at intervals in the fourth year of his disease for relapsing erosions of the lips. He then had no symptoms for a long time and married with the permission of Filarétopoulo. Four months after marriage he showed the same erosions as before his marriage, and his wife had a papular exanthem of characteristic color, glandular swelling, and persistent headaches.

Case III.—Reported by Senger (*Dermatologische Zeitschrift,* 1893-94, Vol. 1, p. 392).

A man 35 years old acquired syphilis (chancre and secondary symptoms) seven years ago and was treated with courses of inunctions and with iodide of potash. He is married and has three healthy children. A few months ago he had a herpes-like eruption on his penis, which healed quickly without treatment. His wife now has condylomata lata and mucous patches. No trace of a chancre could be discovered by careful examination nor by questioning. Sanger convinced himself that there was no extramarital infection; the patients had been known to him for years. The husband had extramarital intercourse once, one and three-quarters years before, but not since.

Case IV.—Reported by Pelizzari (*Riforma Medica,* 1892, part 3, p. 558).

A man acquired syphilis in 1883, and was treated regularly, on account of relapsing secondary symptoms for one year. After that there were occasional relapses, always yielding to treatment, until 1886, when he married. In 1890 he had an attack of influenza, followed by a palmar psoriasis, which yielded readily to specific treatment. In 1891 he had a healthy child. In December, 1891, he had a severe attack of influenza, and in January, 1892, he developed an eruption like that of a recent syphilis in the balanopreputial sulcus. Sexual intercourse was forbidden, but he had connection with his wife between the thighs, and in March, 1892, she showed a healing chancre between the buttocks, and later she developed secondary symptoms.

Case V.—Reported by Filarétopuolo (*La Médecine Orientale,* Paris, 1900, p. 121).

A man had a chancre ten years ago and was treated; he had no symptoms for nine years. Two years ago he had difficulty in chewing, and examination now shows a sclerous plaque at the base of the tongue, with fissures on it, and enlarged papilæ, certainly a tertiary specific glossitis. At the tip of the tongue is a superficial opaline erosion. He has been married six months, and his wife now shows abundant falling of the hair, enlarged glands, and small mucous patches of the pharynx.

Case VI.—Reported by Bovero (*Gazzetta Medica di Torino,* Oct. 27, 1898, p. 841).

A man contracted syphilis in 1888, and in the course of his treatment took 69 mercurial inunctions, and 10.0 g. of iodide of potassium. From 1890 till the date of observation he had no syphilitic symptoms on the skin or mucous membranes. He has a healthy baby, one year old, now with a wet-nurse, and the nurse is healthy * * * On July 8, 1898, he showed a rhagadiform mucous tubercle on the mucous membrane of the left cheek posteriorly, and another the size of a centesimo on the mucous membrane of the upper lip in the middle line. These developed without apparent cause about June 20. He had also a leucokeratosis of triangular shape with the apex forward, on the mucous membrane at the right labial commissure. His wife, seen the next day, had a characteristic chancre on the upper lip in the middle line, dating from June 10. She had enlarged glands, and later developed roseola and mucous patches.

Case VII.—Reported by A. Fournier and Hersher (*Annales de Dermatologie et de Syphiligraphie,* 1900, p. 250.)

A woman 34 years old showed a general maculopapular syphilide, the remains of a chancre on the left labium majus, and enlarged glands in the left inguinal region. She was married, but separated from her husband for three years, and for that period was living with a man who alone could contaminate her genitally. This man contracted syphilis in 1887, thirteen years before, as shown by the records of the hospital. He took pills for six weeks and the iodide of potassium for a year. When examined he had cicatrizing ulcerations on his penis, which had developed about the period of the contagion, two and a half months before.

Case VIII.—Reported by K. Gron ("Studier over gummos syphilis, etc." Christiania, 1897, p. 20).

A woman, married in 1889, bore a healthy child who never showed any sign of syphilis, though repeatedly examined by the reporter. The mother had no specific eruption of the trunk, genitals, or extremities, no loss of hair, adenopathy, no leucoderma, until 1892, when, being about four months pregnant, she was examined by Gron, who found a scaling papular syphilid, the diagnosis being established later by Boeck. She received a moderate treatment with the iodide of potash, without much effect, and a little later there was swelling of the genitals with the formation of mucous tubercles. When she had taken 50.0 g. of potassium iodide the eruption ceased and after taking 96.0 g. the treatment was stopped. In July, 1892, she was delivered of a boy, apparently born about 2-3 weeks too soon, but otherwise normal, and who neither then nor at any other time showed any sign of syphilis. The mother had sporadic papular eruptions, never general, for about six months after parturition. In November, 1894, she had on the inside of the left leg a nodule, sensitive to pressure, with a bluish red discoloration over it; this disappeared under iodide of potassium. She had no eruption after that. During the winter of '96-'97 she was pregnant and was treated with protoiodide. The child has been and is now (6 months old), free from all signs of hereditary syphilis. The husband went through a very malignant syphilis

12 years before his marriage—16 years before the eruption appeared on his wife.

Case IX.—Reported by Gron (*loc. cit.*, p. 17).

A woman, 37 years of age, married 10 years, had a pea-sized ulcer covered with a grayish membrane, on the outer lip of the portio vaginalis. About two months later she developed a characteristic papular syphilide and mucous patches on the genitals. She had been healthy before marriage, but sickly since, and often had headaches, but no eruption and no sores on the throat or on the genitals. She had had three children—the first was born dead eleven years before; the second, born healthy ten years ago, died at 5 years of cardiac paralysis following diphtheria of the throat; and the third, born healthy eight years before, died at 2 years of age of tuberculous meningitis. Her husband had been treated twenty years before for syphilis—chancre and eruption. Except for some brown spots on his back three years before, which disappeared spontaneously, and were hardly of a specific nature, he had no marked eruption on the skin or mucous membranes, except that five or six months before his wife was first seen, he had an exuding abrasion on the glans and on the inside of the prepuce, following the rubbing of a woolen jacket. There was no ulceration, and it healed after being present for fourteen days. With the exception of a slight swelling of the inguinal glands, nothing abnormal was found on his body, the genitals, especially, being completely healthy.

Case X.—Reported by Brouardel ("Le Mariage, nullité, divorce, grossesse, accouchement," Paris, 1900, p. 48).

A patient, treated for syphilis at the time of the Coup d'Etat of December 2, was exiled by the empire and did not return to France until the amnesty. Having had no symptoms for at least six years, he consulted Dr. Martin-Magron, who had treated him before, and asked if he might marry. Receiving an affirmative answer, he married and had four healthy children. When his wife became pregnant for the fifth time he discovered on his penis a small papule, which, occupying the site of the initial lesion, aroused his suspicions. A physician who examined him, and to whom he told his history, called it herpes. This physician was wrong; the so-called herpes was a virulent recurrence of the chancre (*recidive sur place*), taking place twenty-four years after the original infection, and the beginning pregnancy was ended by the birth of an infant with manifest signs of hereditary syphilis.

By inheritance also the virus may be transmitted very late in the disease, especially by the mother, even in the absence of any visible manifestations, as happened in the following cases:

Case XI.—Reported by Drennen (*Memphis Medical Monthly*, 1897, p. 27).

A man acquired syphilis seven years before his marriage to a healthy woman. The first child, born a year later, had hereditary syphilis; became hemiplegic at three years of age, and never recovered. The second child, born three years after marriage, was healthy. Then came two abortions, and a third child, born six years after marriage, who had a syphilitic rash, snuffles and mucous patches. Six weeks after the birth of the last child the mother developed a macular rash all over the body, enlarged glands, sore throat, etc.

Case XII.—Personal communication from Dr. Richard Kalish. A man contracted syphilis when about twenty years of age, and was treated for about three months, after which he declined further treatment. Three years later, having no symptoms, he married, and his wife bore two healthy children. The third child, born five and one-half years after marriage, showed undoubted signs of hereditary syphilis, viz., oral and anal excoriations, snuffles, and a cutaneous syphilide covering almost the entire body. The child improved from the beginning of treatment, which was gray powder by the mouth and inunctions of cod-liver oil, but later died from what the physician in attendance called marasmus. During all this time neither father nor mother showed any sign of syphilis whatsoever, and subsequently two children were born perfectly healthy. All four are now living, and no hereditary taint has ever been disclosed in any of them. The patients are well known to Dr. Kalish, and he could find no reason to suspect marital infidelity on either side.

Case XIII.—Reported by Rabl (*Archiv für Dermatologie und Syphilis*, 1889, Vol. 21, p. 421). A man nine years syhpilitic, and married seven and a half years, had three healthy children. The fourth child was born syphilitic, with mucous patches on the mouth and anus, and a pustular syphilide.

Case XIV.—Observed by Dr. J. Clarence Sharp, in April, 1903, and communicated by him to the author.

Mrs. X. contracted syphilis ten years ago. Her hair fell out at that time, and she had sore throat, off and on, for several years. In 1900 she had what she thought was chills and fever; this left her with some kind of inflammation of the nose, which has been treated off and on ever since. When Dr. Sharp saw her she had pain over the bridge of the nose, nasal discharge, large ulceration on the right side of the septum and a small ulceration on the left side. Her tibiæ were very tender and she had afternoon headaches. She had been married about four years and has never been pregnant. She was put on large doses of the iodide of potash and began to improve at once. She became pregnant and in December, 1903, she was delivered of a fetus of about eight and one-half months, weighing six and one-half pounds. The baby had the old look, a macular eruption over the body, falling out of the eyelashes, and a mucopurulent discharge from the nose. The child was put on inunctions, and improved.

Case XV.—Reported by Lassar (Third International Congress of Dermatology, London, 1896, p. 457). A girl of seventeen was infected by a kiss, and was treated and apparently cured; she married eleven years later and bore a syphilitic child, though no trace of syphilis could be found in her husband.

Case XVI.—Reported by Lassar (*Dermatologische Zeitschrift*, August, 1900, p. 740). A woman acquired syphilis in her first marriage, and was treated under Lassar's direction, with apparently good results. About seventeen years later she took for a second husband a man who had never had syphilis, and who was not infected by her. The first pregnancy went to term normally, but three weeks later the child showed all the symptoms of hereditary syphilis.

Of course the effect of parental syphilis upon the progeny usually diminishes steadily with time, but on the other hand there are recorded many cases like the above where children inherit syphilis from a parent who acquired the disease many years before.

Fournier's[25] statistics of 4,400 cases of tertiary syphilis show that the third year furnishes more cases than any other, that over a third of them occur in the first four years of the disease, and nearly half in the first six years, beyond which time they become much less common. Ehler's[11] statistics of 1501 cases correspond very closely with these figures, but place the onset even earlier, more cases being observed in the second than in any other one year.

If we admit, then, as I think we must, that syphilis may be transmitted many years after the infection by lesions of secondary type,, and by inheritance, and that tertiary symptoms are most frequent in the first few years of the disease, we are forced to admit that the lapse of time since the infection is not by itself a valid argument against the infectiousness of gummata.

It may be objected that in any given case the tertiary lesions follow the secondary, and that the fact that tertiary lesions are present is proof that the disease has lost its contagiousness. This objection is at once overruled by the fact that tertiary and secondary lesions are often known to coexist in the same patient.[12]

If, then, instances of infection from late secondary lesions are fairly common, while infection from a gumma is very rare, the explanation must lie, not in the duration of the disease, but in the character of the lesion. The typical infectious secondary symptoms are the eroded papule and the mucous patch. Both are very superficial, show no extensive degenerative process, and lose their epithelial covering, leaving the deeper parts of the lesion exposed, while they are still in active evolution. The gumma, on the other hand, is a deeper process, and becomes an open sore only after necrosis or caseous degeneration has destroyed not only the epithelium covering it, but presumably also the infectious agent as well. Infection can only be expected when favorable conditions bring about the exposure of the deeper, progressive, active parts of the new growth, as we shall see later, when discussing experimental inoculation.

It is possible, also, that the contagion exists here in much less active form than in the earlier lesions; and we know enough already of the great variations in the virulence of pathogenic organisms to make the possession of the same property by the organism of syphilis seem reasonable. The bacillus of diphtheria is a common example of such variation. Neumann[46] explains in this way the general innocuousness and the occasional contagiousness of gumma. He advances the theory that in the tertiary stage the organism of syphilis, while able to produce symptoms in the victim, is not usually strong enough to carry contagion, but that occasionally some causes not yet understood may stimulate it to all its old virulence.

While the foregoing facts and arguments answer some of the objections urged against the contagiousness of gummata, and explain the rarity of examples of it, they have no value as positive evidence. For this we must turn to clinical observation and to experiment. The perfect clinical demonstration of contagion from a gumma is yet to be recorded; in every instance that I have been able to discover, there is at least one gap in the testimony, and it is not likely that clinical observation alone will ever bring the question to mathematical proof The captious critic can always doubt the integrity of the infected person; and, further, he may claim that what was called a gumma was really a chancre, an instance of reinfection. In ordinary life it is often impossible to be absolutely certain on these two points, but when the balance of evidence points strongly to the accuracy of the report we are bound to give it due consideration, especially if supported by similar and independent occurrences. To quote Feulard, "The smiling scepticism, which was all too long the fashion where syphilis was concerned, and which finds it simpler to doubt the morality of a patient than to seek another explanation for facts which contradict received ideas, is no longer held in honor."

Aside from the 45 observations brought together by Feulard and by Tarassevitch, and the sixteen recorded above, of transmission of syphilis by late secondary lesions and by obscure and undetermined means, I have collected the reports of 25 cases bearing on my subject. Six of them are given by Tarassevitch as examples of tertiary contagion; the remaining 19 are from the most various sources. Some are recorded with such evident care and attention to detail that they are most convincing, while others are so fragmentary that by themselves they are of no value.

Cases in which the infecting lesion is not mentioned:

Case XVII. — Reported by Josef von Broick ("Ueber extragenitale Initialsklerosen," Inaugural dissertation, Bonn, 1888; Abstracted in *Archiv für Dermatologie und Syphilis,* 1889, Vol. 21, p. 883).

A toothless old woman, with gummata of the skin of the leg, suckled the milk from a woman's breast. The woman developed a chancre of the breast, followed by secondary symptoms, and in turn infected her husband, either by kissing or by the common use of a fork, spoon, or similar article.

Case XVIII.—Communicated by Goldzieher and Saenger to Delbanco, and published by the last in the *Monatshefte für praktische Dermatologie,* June 14, 1904, p. 591.

A merchant 32 years old had a tubercular syphilide on the right leg shortly after his return from his wedding trip. Nine years before he had had a peculiar red spot on the thigh, about whose nature two physicians, whom he had consulted, were not sure, but which was soon followed by general swelling of the glands, especially of the neck. Specific treatment was instituted, in which he took much iodine, but only a few inunctions. There were no other manifestations, except fainting spells about three months before his marriage. A few weeks after his marriage, his wife had a general maculopapular eruption which relapsed frequently. Within six months, the husband developed syphilis of the spinal cord, which took the form of acute transverse myelitis, and which was cured entirely by mixed treatment. Delbanco declares that both the patients were well known to him, and that he has no doubt that it was a case of infection in the gummatous period.

Case XIX.—Reported by Jacob Halpern (*Archiv für Dermatologie und Syphilis,* 1894, Vol. 28, p. 67).

A man, 32 years old, had a chancre 14 years before his marriage. Seven months after his marriage he had a serpiginous ulcerating syphilide of the right thigh. Ten months after the marriage, a full-term apparently healthy child was born, who died of convulsions in its sixth month. Nineteen months after marriage, the wife showed an already partially cicatrizing cutaneous gumma of the right lumbar region. She came of a healthy family who showed no trace of syphilis, and she had never before noticed any symptoms referable to that disease.

Cases in which no infecting lesion could be found, and in which the semen must be suspected:

Case XX.—Reported by Biron (*Medycyna,* Jan., 1896, Vol. 31, p. 25).

A man contracted syphilis in 1878; it ran a mild course, and was treated systematically for three years. There were no more symptoms, and in 1889 he married, after getting the consent of two physicians who examined him and found nothing wrong. Two months after being married his wife developed a papular eruption, which increased in the number and the size of the lesions until Biron saw her three months later—five months after her marriage. At that time she had a gereral lenticulopapular erup-

tion, with mucous patches on the mouth, pharynx, rectum and pudenda. Only the cervical glands were much enlarged, and Biron could find no initial lesion. She was not pregnant. The husband showed only a slight hardness of the right epididymis (the remains of an old gonorrheal epididymitis), unequal pupils and dizziness. The last two symptoms disappeared under mixed treatment. Biron says he convinced himself that the woman was infected by her husband soon after marriage, the symptoms appearing two months after that date; and that extrasexual infection could be excluded by the fact that all the people around her were well. He expresses the belief that the infection was by means of the semen, and urges the fact that by analogy it is reasonable to suppose that the semen may contain the contagium, though the testes be normal, just as the urine may contain tubercle bacilli, though the kidneys be normal.

Case XXI.—Reported by Kromayer (*Dermatologische Zeitschrift*, 1897, Vol. 4, p. 708).

A man contracted syphilis in 1867, for which he took several courses of inunctions. Early in the seventies, he had dry patches on both palms, which disappeared under a course of inunctions toward the end of that decade, only to return a few years later to persist until the present time (1897). About the middle of the seventies he married, and his wife bore him three healthy children, the youngest 8 years old, with no abortions or premature births. His wife had a recent syphilis when Kronmayer saw her, psoriasis palmæ, condylomata lata and a papular exanthem, following swelling of the inguinal glands. Kromayer first thought of extramarital infection, but convinced himself that his suspicion was unfounded. The man stated that about the time of the supposed infection, four months before, he tore his rather narrow and rigid prepuce in coitus (which was practised rather seldom) so that it bled a little. Examination of the man showed only the eruption on the palms, and the somewhat narrow, thick and rigid prepuce.

It will be convenient to discuss these five cases together, for although three of them showed tertiary lesions, it is very improbable that these were the source of contagion. In the first of the group it is fair to assume that the old woman had sores of some kind in her mouth, as well as gummata of the leg. The remaining four are much less easy to explain. Extramarital infection was thought of, and excluded, as far as this is possible, in all of them. The possibility of an unnoticed extragenital chancre must be considered in all of them. But the onset of the symptoms soon after exposure to a man known to have had the disease, in cases 18 and 20, and the particular involvement of the inguinal glands in Kromayer's case, point strongly to sexual contamination. Even in the absence of any visible lesion at the time of the examination there are five ways in which the poison might have been conveyed: by the blood, by the secretion of an erosion on the penis, or by that of a herpetic vesicle, either of which might easily escape the notice of the patient, and heal before the examination by the physician; by the secretion of a mucous patch within the urethra, and by the semen. Infection by the blood can probably be excluded; at the best it is not proven in such old cases, and other explanations are simpler. Infection from a transitory erosion or from a herpetic vesicle is quite possible, and could be excluded only by the most careful examination; examples of both have been given above, and others are included in Feulard's statistics. In this connection Mauriac[88] says: "I have seen syphilis transferred nine years after marriage by a simple erosion of the scrotum. It is my opinion that it is not only clearly syphilitic lesions that may infect, but any common erosion occurring in a syphilitic; and in this respect herpes is in the first rank." In this connection the following report by Fleugel[21] is of interest: A man of 29 years of age, in full secondary eruption, had on the under surface of his penis and on his scrotum several pea-sized mollusca contagiosa, whose contents were partially suppurated. In this pus two specimens of *Spirochæta pallida* were found. Infection from a mucous patch within the urethra may be the true explanation, not only of these cases, but of almost every other case of genital contamination as well, and it would be very hard to exclude it. Infection by the semen is not generally considered possible; but there is some evidence for the opinion that the finished product at least is capable of transmitting the disease. Finger[18] has reported the successful inoculation of a monkey with the semen of a man who had had syphilis for three or four months, and whose eruption was just receding. It must be remembered in this connection that Neisser[48] found that of all the internal organs of syphilitic monkeys, it was the testicle whose inoculation was most surely followed by the development of a chancre. This possibility of infection by semen, or by semen mixed with the secretion of a urethral mucous patch, must be remembered in discussing all the cases of genital infection, and it adds greatly to the difficulty of the subject.

Cases of infection from a gumma of the penis:

Case XXII.—Reported by Landouzy (First International Congress of Dermatology, Paris, 1889, p. 713).

A man about 50, who, when about 30 years old, had been treated by Ricord for an infecting chancre of the penis, presented himself to Dr. Landouzy with a serpiginous suppurating ulcer between the glans penis and the prepuce, which was diagnosed as syphilitic gumma, and the diagnosis confirmed the same day by Professor Fournier. It is not stated whether the gumma developed on the site of the old chancre. There was no other lesion than this gumma, which was about the size of an almond. The patient said that it had appeared slowly, increasing progressively after frequent and ardent sexual intercourse with his young wife. The wife was examined by Landouzy 48 hours after the husband, and showed groups of enlarged but painless lymphatic glands in the neck and in the groins, especially developed in the right groin; and a superb almost general roseola. No mucous patches were to be found, and although there was a small superficial right vulvar erosion, Landouzy could not make certain of the initial lesion. The woman said she had had a small papule on the right labium majus, but neither the site, size, date of appearance, nor nature of this papule could be established. Several months later, in spite of treatment with iodine, she had mucous patches on the tongue, throat, vulva, and anus. The gumma of the penis healed rapidly under treatment, and no other symptoms appeared. The duration of the syphilis at the time of transmission was about twenty years.

Case XXIII.—Reported by Ehlers (Vierter Kongress der Deutschen Dermatologischen Gesellschaft, Breslau, 1894, p. 309).

I give the report verbatim: "Three years ago I saw a man, married two years after the infection, having been treated only once with mercury; his wife remained well and bore two healthy children. When the man came to me for treatment, eight years after the infection, and six years after his marriage,

he had a gummatous ulceration on his penis" (it is not stated whether this was at the site of the old chancre), "which healed quickly under treatment with mercury and the iodide of potassium. But two months later his wife came to me for treatment—surely infected by the husband—with a universal papular syphilide, and the third child was born syphilitic. If the gummatous ulceration of the penis is not contagious, I cannot explain this case in any way, for it was not a reinfection in the man; no secondaries followed, and six months later he came to me with gummatous orchitis."

Case XXIV.—Recorded in 1875, by Fournier, and communicated by him to Feulard, and reported by the latter (Third International Congress of Dermatology, London, 1896, p. 478).

Mr. and Mrs. X. consulted Professor Fournier June 21, 1875. They were strangers, and had just taken a course of sulphur waters in France. This treatment was recommended by the physician of their country for Mrs. X., who in the preceding March had all the symptoms of a syphilitic infection, and at the time of her visit to Fournier she still had patches on the tonsils. According to her own physician, her syphilis had certainly been given her by her husband. Mr. X. had syphilis in 1861; he was treated at Aix-la-Chapelle, and for thirteen years had no symptoms; in August, 1874, he had on his penis an ulcer which was considered a new chancre, which left a scar, and which was believed by Fournier to have been a tertiary syphilide. This ulcer, which reopened from time to time, was open in February, 1875, when Mr. X. had connection with his wife. It was not followed by any secondary symptoms, and at the time of his visit to Fournier Mr. X. had a slight facial hemiplegia.

Case XXV.—Reported by A. Sack (Verhandlungen der Gesellschaft Deutscher Naturforscher und Aerzte, Hamburg, 1901, Part 2, p. 424).

A newly-married man who had had a mild and imperfectly treated syphilis about ten years before, developed a gummatous ulcer on the frenulum, at the site of the original chancre. Reinfection was excluded by the clinical form and course of the ulcer, and by the result of treatment; it was a tubercular ulcerating syphilide, followed by no involvement of the glands, skin or mucous membrane, and it healed in three weeks under large doses of the iodide of potassium given internally and weak bichloride dressings locally. The wife, scarcely six weeks married, became pregnant and developed on the corresponding site—the posterior commissure—a well-marked chancre, with enlarged inguinal glands, followed by a general syphilitic eruption, anemia, headache, and general adenitis. At the sixth month, in spite of energetic treatment by mercurial inunctions, she aborted, the fetus being dead.

Case XXVI.—Reported by Delbanco on March 17, 1903, before the Biological Section of the "Hamburger Aerztliche Verein" (published in the *Muenchener medizinische Wochenschrift*, No. 16, 1903, and more fully in the *Monatshefte für praktishe Dermatologie*, June 15, 1904, p. 586).

A man 48 years old, who fourteen years before had been treated by a course of inunctions in a Hamburg hospital for chancre, presented a crateriform ulcer at the corona glandis, close before the opening of the urethra, involving also part of the glans. It was about the size of a five-pfennig piece, with an uneven base covered with pus, and with thick infiltrated and raised border. A second ulcer, about the size of a two-mark piece, otherwise like the first, occupied the fold between the penis and the scrotum. The patient thought the chancre had been near the frenulum, but did not remember exactly. Careful examination of the patient showed nothing else abnormal—whether of skin, mucous membrane, lymphatic glands, or internal organs. He was a hard drinker, and of loose sexual habits. He had returned from a business journey with the ulcer on his penis, but in spite of it had sexual intercourse with his wife. Shortly after the wife had severe headaches, and a very general syphilitic eruption. Delbanco found her—a woman 50 years old, living in a second marriage—suffering from a general roseola, papules on the vagina, anus, and tonsils, enlarged glands, severe anemia, and rheumatic pains, increasing at night. A very careful examination failed to reveal any trace of a chancre, whether genital or extragenital, except a slight edema of the left lesser lip. The woman stated, however, that her husband had attempted coitus in anum—though whether the act was completed is uncertain—and that before the outbreak of the eruption she had had severe pains in the anus. Although she did not live happily with her husband, she gave her word of honor that she had had sexual intercourse with no one else.

There are certain objections common to all these cases; there are always the possibilities that the woman was unfaithful, that the so-called gumma was in reality a chancre, an instance of reinfection, and that the semen, a urethral mucous patch or a transitory secondary lesion of the penis may have been the source of infection. In answer to the first two objections, we can only appeal to the discernment and the skill of the reporter; he may have been deceived, but if he is a man of wide experience and acknowledged ability, he must be listened to. The last objection is as yet unanswerable. If the semen is sometimes infectious, if mucous patches may exist within the urethra, it may well be that one of these conditions was present in each case where a gumma seemed to be contagious. Further observation and experiment are necessary to settle the question. There are other weak spots in nearly all the cases, for in only one was the site of the chancre discovered; the rest may have been cases of extragenital infection, from some unknown source, the chancre healing unnoticed. Nevertheless the outbreak in the woman closely following the outbreak in the man is exceedingly suggestive, especially in those cases where the man and woman had lived together for years before, in apparent health. Delbanco's case suggests the possibility that the husband had intercourse with a syphilitic woman and carried the virus from her to his wife, being of course immune himself. Such cases have been reported, but they must be very rare, for Salmon[52] and Neisser[43] both found that the organism loses its virulence very quickly, often in six hours, and this even when kept moist. Sack's case is about the most complete of any, but even here the objections first mentioned cannot be entirely avoided.

Cases of infection from a gumma elsewhere than on the penis:

Case XXVII.—Reported by Lassar (*Dermatologische Zeitschrift*, August, 1900, p. 740).

A mother who had had syphilis for seven years had gummatous ulcers of the leg, without knowing their nature. She brought her six-months-old daughter, with a well-marked chancre on the labium majus. The child had infected herself with the dirty bandages of the mother, whose bed she often shared.

Case XXVIII.—Reported by Lassar (Third International Congress of Dermatology, London, 1896).

A shoemaker, 43 years old, infected fifteen years

before, and now having ulcerating gummatous tubercles on his under lip, brought his five-year-old daughter, who had recent papules about the mouth and a papular eruption on the body.

Case XXIX.—Noted by Paul Claisse in 1876, communicated by him to Tarrasevitch, and published by the latter in his thesis, 1897, p. 96.

A man contracted syphilis at 21 years of age, the chancre being followed by secondary eruptions which recurred for several months. At 27 he married, with the consent of a physician. Two years later his wife was confined at term, and died ten days later of puerperal fever. The child died at five years, of diphtheria. At 39 he married again, and passed three years without incident. Then he noticed at the right labial commissure a slight induration, which became elevated, and finally ulcerated. It was treated only with a boric acid wash, and closed gradually, leaving a pale star-shaped scar about a centimeter in diameter. As the ulcer closed, his wife developed a chancre of the lower lip, and a few weeks later a roseola and mucous patches. All the lesions disappeared under treatment with mercury and iodine.

Neither of these cases of Lassar's is at all convincing. They may be examples of tertiary contagion, but the evidence is very meager. Indeed, in the first case it is altogether more probable that the mother had contagious patches in the mouth, from which the virus might very easily have been carried to the child by means of pins or clothes. Claisse's case, reported by Tarasservitch, is much more to the point; it is altogether probable that the woman contracted the disease from the lesion on her husband's lip, but the character of the lesion is very doubtful, for the description might apply to a chancre quite as well as to a gumma, and there is no evidence given to prove that it was not a reinfection.

Cases of infection from tertiary lesions of the mucous membrane of the mouth:

Case XXX.—Reported by A. M. Sigmund (*Humboldt Medical Archives,* April, 1868, p. 65).

A girl of 17 kissed "a man whom I knew to have been laboring under tertiary syphilis and who had at that time some indolent sores on the inside of his lips," and she held between her lips a cigar-holder which he had just been using. Soon after she developed a chancre of the lower lip, which she in turn communicated to a third patient, who later developed typical secondaries.

Case XXXI.—Reported by Sanguineti (Atti della Società italiana di dermatologia e sifiligrafia, t. 3, p. 125. Abstracted in *Annales de Dermatologie et de Syphiligraphie,* 1901, p. 198).

In 1889 a man acquired a chancre, followed by roseola and mucous patches, and the next year by syphilitic retinitis. He was then free from symptoms for three years, and later married and had two healthy children. In May, 1898, he had a gumma of the tongue about the size of half a nut, with diffuse interstitial glossitis, both of which healed rapidly under mercurial treatment. At the same time his wife presented mucous patches of the vagina and anal region, a maculopapular syphilide, palmar plaques, intense headaches, and cervical adenopathy. Sanguineti declares that he could find no other origin for the syphilis of the woman than the lingual lesions of the husband.

Case XXXII.—Reported by Pelizzari (*Riforma Medica,* 1892, part three, p. 557).

A man was treated for syphilis in 1881, by Pelizzari, whom he again consulted in 1892, on account of silvery patches on the lips, cheeks and tongue, asking if such lesions could be contagious. He had married in 1891, and toward the end of December his wife began to suffer from sore throat and slight general weakness, followed by great pain, violent fever, and eruption. Pelizzari saw her February 29, 1892, and found her suffering from a recent syphilis. He thought that the right tonsil was probably the port of entry, on account of its size and hardness in comparison with the left, the greater swelling of the glands on that side of the neck, and the almost entire absence of lesions on the genital region. The woman was of good family, had not been away from home, and Pelizzari was convinced that she contracted her syphilis from her husband, in whom the virus had been stimulated by an attack of influenza just before her infection.

Case XXXIII.—Recorded by Landouzy, communicated by him to Feulard, and reported by the latter at the Third International Congress of Dermatology, London, 1896, p. 478.

Mr. X., 34 years old, had when quite a young man, a rather severe blenorrhagia, and later an erosion in the left balanopreputial fold, which a physician did not consider serious, and which nevertheless was a long time in healing, being hollowed out to the size of a lentil. It left no appreciable scar. He had been married about four years when Landouzy saw him, and in that time had had nothing on his body. He denied all intercourse since marriage except with his wife, and would entertain no suspicion of her fidelity. Up to this time his wife had never been pregnant, though very healthy, and "formed to have a dozen children," as a gynecologist declared when consulted on this point. Dr. Landouzy was called to see the wife on account of a general eruption and found a disseminated papular syphilide, small nonindurated patches beginning to form on the labia majora, enlarged perimaxillary, cervical, axillary, and inguinal glands, especially at the border of the jaw, at the right angle of which was an indolent, cold gland, larger than any other on the body. The uvula was covered by a typical opaline patch; the tonsils were enormous, verrucous, the right especially looking like a big raspberry. For two weeks she had suffered from fever, loss of appetite, lassitude, headache, and malaise. The husband, carefully examined that day and the following, showed absolutely nothing abnormal of skin, mucous membranes, or lymphatic system, except for a smooth tertiary glossitis, without nodules or furrows, bordered by psoriasiform plaques. He had smoked cigarettes for sixteen years, but had suffered no inconvenience, and declared that his tongue had been in its present condition only a short time. For several weeks he had had frequent intercourse with his wife (whose vulvar lesions were comparatively slight), but he had no lesion on his penis. The woman was shown to Professor Hardy, without history, and he made the diagnosis of secondary syphilis; chancre of right tonsil, probable port of entry. Professor Fournier saw the husband, and in view of his excessive smoking, made some reserve about a positive diagnosis of tertiary glossitis; but when the whole history was given, including his indemnity while cohabiting with a wife in full secondary eruption, acceded to the diagnosis of tertiary specific disease of the tongue. Under specific treatment the woman recovered rapidly, and after the husband had taken potassium iodide for several months she became pregnant, and all went well till the fourth month, when, in consequence of a mishap when getting into a carriage, she miscarried.

Case XXXIV.—Reported by Fournier (First International Congress of Dermatology, Paris, 1889, p. 717).

"A young man contracted syphilis fifteen years ago, which ran its ordinary course. He was treated, recovered, and asked permission to marry. After his marriage he had pulmonary symptoms which were specific in all probability, and then a sclerous glossitis: his tongue was indurated and he had frequently little erosions. He was a heavy smoker. I told him the dangers which threatened his wife. Two years later he brought her to me; she had a chancre of the lower lip, and very characteristic secondary symptoms. He himself had only insignificant erosions of the tongue. It is unnecessary to add that his wife was above all suspicion, and besides, this coincidence between labial chancre and lingual erosions is sufficiently significant."

Case XXXV.—Reported by Jullien ("Vieilles Veroles," Kaposi Festschrift, *Archiv für Dermatologie und Syphilis,* 1900, p. 15).

A man 32 years old, who had been infected sixteen years before, had a glossitis of very late type; it seemed so old that another physician had not thought it necessary to give specific treatment, and allowed marriage. The glossitis was cured by a few injections of calomel; but one day the wife came with her husband, and Jullien recognized in her a paralysis of the third pair; the tongue, apparently so inoffensive, had made a victim.

The first of the cases, Sigmund's, is interesting chiefly on account of the early date at which it was published, when the doctrine of the contagiousness of secondary lesions was still fresh. It is a pity that there is so little said about the course and appearance of the disease in the young man, for as the record stands, the opinion is almost irresistible that "the indolent sores on the inside of the lips" were mucous patches. Jullien's case proves at least his own belief in the contagiousness of the late lesions; as an argument it has little weight save that of the author's authority, but as an example it is interesting.

The remaining cases can all be accounted for by accidental infection from some unknown source, which indeed is not at all uncommon. Still the development of a chancre in a wife soon after late lesions in a husband who had had no symptoms for years is much more suggestive of cause and effect than of coincidence. These cases have also the advantage that there is no question of infection by a hidden mucous patch, since the entire mucous membrane is accessible for inspection.

Cases of inoculation of physicians in the practice of their profession:

Case XXXVI.—Reported by Bumstead (*Humboldt Medical Archives,* 1868, p. 274).

"A well-known surgeon of the West was called upon to operate upon a case of extensive syphilitic necrosis of the cranium in a patient who had had no secondary symptoms for a period of two years. One of the surgeon's fingers was abraded, and at this spot a chancre developed a week or two afterwards, and was followed by the usual train of symptoms. Such was the history communicated to me by this surgeon, who was also confident that he had not been brought into contact with a case of syphilis before for several years and could have contracted the disease only from this operation. His age, standing, and powers of observation are such as to add great weight to his statements, and I am inclined to believe his opinion correct, yet the possible sources of error are so numerous that I would not adduce the case as one beyond question."

Case XXXVII.—Reported by Brandis (*Deutsche medizinische Wochenschrift,* 1898, p. 329).

A case of chancre of the finger in a surgeon, following an operation for necrosis of bone.

Cases XXXVIII, XXXIX, and XL.—Reported by Brandis (*loc. cit.*).

The author reports three cases of chancre of the finger in surgeons, following the examination of or operation on "those difficultly healing ulcers of the rectum, which give so much trouble and not seldom lead to stricture, and (at least as far as I have observed) are always accompanied by profuse and putrid suppuration." He gives no further details of the sources of the infection.

Case XLI.—Reported by Lydston ("The Surgical Diseases of the Genitourinary Tract, etc.," 1904, p. 361).

A physician inoculated his finger while operating upon a rectal fistula in a patient suffering from tertiary syphilis. In due time a chancre appeared, and was followed by a well-marked development of secondary symptoms. He died, finally, from cerebral syphilis.

These cases of "professional syphilis," as it has been called, are of great interest, but the data given are so meager that they are not convincing. It is particularly to be regretted that we have no exact information of the age of the syphilis from which the contagion was supposed to spring: for as the records stand, infection through the blood was quite possible. In connection with the first two cases, however, it should be remembered that bone marrow is one of the few internal tissues of infected monkeys which Neisser[43] found capable of transmitting the disease.

Experimental inoculation of the products of gummatous lesions was attempted many years ago, and always without success. Diday, Ricord, Boeck, Baerensprung, Sarrhos, Tanturri, all tried repeatedly, and all failed. But closer examination robs these experiments of all their value, as evidence against the contagiousness of gummata, for, in nearly every instance, the matter was reinoculated on the patient from whom it was taken, and in other cases it was inoculated on patients already suffering from syphilis. It must be remembered also that at the time these experiments were undertaken, an inoculation with syphilitic material was considered positive only when a pustule developed within a day or two of the experiment; the existence of the primary incubation period, the lapse of three or four weeks between the exposure and the development of the chancre, was not fully established, and Ricord accounted for all the cases where it appeared to occur by imperfect observation. Is it any wonder that under these circumstances inoculation with gummata should have seemed unsuccessful? Even if a chancre had appeared in some of the very few cases where healthy subjects were used, it would have been overlooked. We are quite justified then in throwing out all these early experiments. They were repeated later, however, on subjects free from syphilis, who were watched for weeks afterwards, and with the same negative results. Thus Finger,[15] in 1887, reported a series of ten such inoculations, using, to quote his own words, "gummatous pus, the degenerated caseous masses, not the true secretion of the gumma." This statement of the material used gives the explanation of his failure and the failure of so many others, and of the fact that so many men with gummatous lesions do not infect their wives. As has been pointed out repeatedly,[40] an ulcerating gumma is a degenerating lesion, and might be expected to be free from its specific organism, just as the pus of an old gonorrheal pyosalpinx is sterile. It is only in the progressive developing parts of the gumma that the active contagium may reasonably be looked for. Yet, even if such material were used, many inocula-

tions might fail. The results of these early investigations are often quoted against the contagiousness of gummata, but people forget that years ago the experimental inoculation of matter from primary and secondary lesions was often equally unsuccessful. Fournier[22] quotes Rattier, Sarrhos, Cullerier, and Puche, as having failed many times in attempting to inoculate upon healthy subjects the material from various forms of the secondary eruption, and from hard chancres, and states that he himself saw the failure of the attempt to inoculate material from a hard chancre upon a healthy man.

While these experiments were going on, the attempt was being made repeatedly to find an animal susceptible to syphilis. Amongst a host of animals used, the monkeys seemed to be the best, and from Cullerier in 1845 to Nicolle in 1889 a number of investigators found that when the secretion of a chancre was inoculated upon these animals, they developed about three weeks afterwards a very suspicious sore at the site of the inoculation; and some few observers even reported a secondary eruption; but the results were unconvincing, the eruption was of doubtful character, and there was no way of proving that the so-called chancre was really syphilitic at all. The matter stood in this unsatisfactory condition until Metchnikoff and Roux, in December, 1903, announced the successful inoculation of anthropoid apes, and experimental syphilis was again a laboratory possibility. Metchnikoff continued his work, and others corroborated it, notably Lassar, Neisser, and Thibierge. It is now firmly established that the higher apes, especially the chimpanzee, are inoculable with human virus, that the inoculation wound heals without incident, and that after a period of incubation averaging about four weeks, an indurated sore forms at the site of inoculation, soon followed by local adenopathy, and later in some cases by a papular eruption. These products may be reinoculated on other apes, leading to exactly the same development. When the human syphilitic virus is inoculated on lower monkeys, the action is somewhat different. The inoculation wound heals as kindly, the period of incubation is practically the same, but adenopathy is generally absent, and there is no general secondary eruption, thus confirming the results of the earlier investigators. Yet the disease is still syphilis, for if the initial lesion so produced upon a lower monkey is inoculated upon an anthropoid ape, it causes exactly the same train of symptoms that follows the inoculation of human virus; and as in man, one attack of the disease protects the individual against all subsequent exposures. Although the lower monkeys do not invariably react to the human virus, still when they do react, the clinical appearance and the course of the resulting lesion are so uniform and so characteristic that they form an excellent proof of the material used for inoculation.

The first recorded attempt to inoculate gummatous material on monkeys, so far as I have discovered, was made by Salmon[51] and published by him in 1904. He inoculated two monkeys, a macacus cynomolgus and a macacus sinicus, on several parts of the skin, with pus from a gummatous ulcer on the arm of a man whose syphilis dated back eight years. Both of the inoculations failed. Sixty-six days later, the monkeys were inoculated with material from the secondary eruptions of two men with recent syphilis. One of the monkeys died of some intercurrent disease, the other (macacus cynomolgus) developed two typical chancres of the palpebral conjunctiva, and submaxillary adenopathy.

Metchnikoff[39] inoculated on both eyebrows of a chimpanzee the scrapings of an ulcerated gumma of the base of the nose. There was no result, and thirty-seven days later he inoculated on the same animal the virus from the chancre of another chimpanzee, mixed *in vitro* with the contents of a gumma of the arm. Thirty days after the second inoculation a typical chancre developed.

The cause of failure in all these cases was the same as in the earlier experiments with human subjects; that is, the material used was the degenerate product of a retrograde metamorphosis, not the secretion nor the substance of an active growing lesion.

The first successful inoculation of gummatous material which I have found recorded was reported by Finger[17 19] to the *Wiener dermatologische Gesellschaft*, May 24, 1905. He used the contents and scrapings from the hard border of a softened but not yet ulcerated gumma on the leg of a woman who had an old unrecognized and untreated syphilis, which dated back apparently to a period seventeen years before. This was inoculated in several places on a cynocephalus hamadrvas. The wounds healed without incident, but twenty-four days later one of the spots developed a red papule, which five days later ulcerated and then covered itself with a crust, and which healed after sixteen days. Other points of inoculation followed practically the same course, and one of these, excised and examined microscopically, showed the usual structure of a chancre as seen in men and apes. A second inoculation on the same monkey, forty-two days after the first, with matter from a human secondary lesion, was unsuccessful. The experiment was repeated on another monkey, with the same results, but the details of this case are not yet accessible.

Neisser[43 44] also reports several positive inoculations with tertiary material, and in one case the syphilis of the patient whose gumma furnished the infectious material was ten years old.

These experiments are the more convincing as Finger has been forced by them to give up his old contention[16] that gummata are caused by the toxins left in the system by an old syphilis, and that they do not contain the virus, while Neisser was very slow to acknowledge the syphilitic character of the lesions observed in monkeys.

It remains only to mention the spirochæta. This organism is found in practically every chancre and mucous patch, if the search be continued long enough; and with improved technique the number of failures reported grows less and less. Even many years after the infection, the spirochæta is present in secondary lesions, as Tomasczewski[57] reports it in three cases four, five, and seven years, respectively, after infection. Flexner[20] reports finding numerous spirochætæ in the blood from a macule of a syphilitic infant whose mother's syphilis dated back eight years. But in spite of the long period of their possible life in the body, they have never certainly been found in gummata, and as the experiments of Finger and of Neisser prove that a gummata may be contagious, we must explain the apparent contradiction or else deny the etiological significance of the discovery of Hoffmann and Schaudin. The solution is afforded by analogy with lupus vulgaris. This disease is caused by the growth of *Bacillus tuberculosis* in the skin, and pieces of lupous tissue, inoculated in guinea-pigs, reproduce tuberculosis; yet it is exceedingly difficult to find the bacilli in the lupous tissue, their number is so small, and they are so widely scattered. So in syphilis, if the spirochete is the specific organism of syphilis, it must exist in gummata, though in such small numbers that up to the present it has escaped detection.

These are the data from which we may decide. The clinical evidence seems at first to be contradictory; there are many authentic instances of exposure to tertiary lesions without contagion resulting, and a few instances of such exposure followed by contagion. The escape in the first class has been fully explained, I think, and these cases have therefore but little weight; in the second class, the infection may be explained by accidental inoculation from an unknown source, but as the cases accumulate this explanation becomes more and more unsatisfactory, until we must acknowledge that the balance favors a causal relation between the exposure to a tertiary lesion and the development of a chancre. About the most convincing are those cases in which a woman has lived with a man for months or years, in perfect health, and then develops a chancre soon after an outbreak of tertiary symptoms in her husband. These cases are now sufficiently numerous and reported in sufficient detail, I think, to bring conviction even to a careful mind; but they do not amount to proof. The experiments, on the other hand, are conclusive. They rest on the authority of well-known and reliable observers, one of whom was forced by them to give up the opinions he had held and defended for years. They prove that a gumma may be capable of transmitting the disease. Whether a gumma is always contagious is a very different question. It is altogether probable that the living, growing part, the border, is always infectious, and that the rarity of examples of infection is due to the fact that the organism is present in such scanty numbers and has so little chance to reach fertile soil. This belief, however, is not proven, and the phenomena of apparent harmlessness and occasional virulence are susceptible to other interpretations; first, the organisms may vary in their virulence, as above mentioned; and second, the gumma may be a product of the action of toxins in which the organisms of syphilis may be present from time to time but which exists independently of their presence. These questions will probably find their explanation in further inoculation experiments; in the meantime, the first explanation is the best, because it fits all the facts observed, and because it is the simplest. In any case, the practical lesson is the same—so long as a man shows any sign of syphilis, so long he must be considered a source of danger to the community.

My thanks are due to Dr. L. Duncan Bulkley for his advice and counsel in the pursuit of such research; to Dr. Boleslaw Lapowski for many practical hints and the translation of one of the case-reports, and to Dr. Sharp and to Dr. Kalish for the privilege of reporting their cases.

Treatment of Boils.—Bulkley recommends an ointment of carbolic acid, 5-10 grains; fl. extract of ergot, 1-2 drams; starch, 2 drams; zinc oxide, 2 drams; and rose-water ointment, 2 ounces. It is spread upon the center of a moderately thick layer of absorbent cotton, several times the size of the inflamed area, and secured with strips of adhesive plaster.—*International Journal of Surgery.*

CARBON-DIOXIDE GAS RETENTION AS A FREQUENT FACTOR OF DISEASE.

By LOUIS BRADFORD COUCH, M.D.,

NYACK, N. Y.

At the conclusion of an article published in the Medical Record of June 23, 1905, on "Formic Acid in Rheumatic Conditions," I gave a brief résumé of some discoveries I had made concerning the etiology of this disease as a result of four and one-half years' study and experimentation:

1. That uric acid is a product, not the cause of rheumatism.

2. That all varieties of rheumatism are caused by a carbon-dioxide, or rather, a carbonic-acid toxemia, due largely to fermentation of starchy substances in the stomach and bowels through improper insalivation and mastication of these substances and the pernicious use of liquids during and after meals which greatly dilute and weaken the ferments designed to digest such substances.

To-day I not only reiterate those statements, but declare furthermore that many of the diseases with which mankind is afflicted are primarily due to retention of the same poison in the system through failure of one or more of the excretory organs to perform their function of elimination. Disease germs, though impotent and powerless in conditions of perfect vitality, become active as roused lions when vitality is impaired. Lowered vitality or anemia comes first as an important etiological factor in the production of nearly all the diseases to which human flesh is heir. From time immemorial man has recognized and dreaded the dangerous effects of suppressed perspiration, but throughout the ages no one has ever recognized the toxic factor of perspiration which, when retained within the system, produces so much pain, suffering, and death. The author has after much study and experimentation found this potent factor of disease to be carbonic acid, the only poisonous constituent of perspiration.

That there may be a proper illumination of the subject and no misunderstanding; that the profession may look at this subject from my viewpoint, I ask the reader's indulgence for relating certain facts with which he is already familiar. To maintain animal heat, an oxidation of food products and other hydrocarbon substances is constantly going on within the system, resulting in the formation of carbon dioxide gas. This gas in the presence of water forms carbonic acid ($H_2O+CO_2=H_2CO_3$). This acid is a stable compound, present in the system in ever-varying quantities and is eliminated by four great vitally important organs of excretion, the lungs with their 1,800 square feet of mucous surface, the skin with 11,000 square feet of cutaneous openings of sweat glands, the mucous membranes of the stomach and bowels, and lastly the kidneys whose secretions always contain it in variable amount. If the kidneys suspend their function of excretion, convulsions result; this is due not to uremia but to carbonic acid retention. If the skin function of any locality is suppressed, the subcutaneous tissues and adjacent mucous membranes suffer a local toxemia in consequence. Expose the uncovered head to a cold draught of air, suppressing perspiration, and sneezing with running of the nose give instant warning that one has taken "cold" and that an attack of acute nasal catarrh has begun. It may extend to the aural mucous membranes and catarrhal deafness result. Germs, however, have nothing to do with these pathological processes.

A draught of air on a perspiring neck, shoulder, or lumbar region produces a rheumatism of the muscles beneath—a local toxemia—almost at once. Tonsillitis on the right or left side, spasm of the glottis, and rheumatic sore throat are similarly produced. If one leaves off the usual chest clothing, undershirt or overcoat, and exposes himself to a cold draught, pleurodynia, pleuritis, laryngitis, catarrhal bronchitis, or pneumonia will quickly follow as a direct result of suppression of perspiration. The bacillus of pneumonia cannot be considered as the sole active, primary cause of any of these various diseases, but on the contrary all are produced by one essential cause —exposure to cold, suppression of the cutaneous exhaling function resulting in a localized carbonic acid toxemia. Soldiers after long marches and football players after strenuous games suffer from albuminuria, of which an increase of oxidation of hydrocarbons producing abnormal amounts of carbonic acid in the blood is manifestly the cause. After constant study of this subject for many years, I am convinced that all pains, neuralgic, rheumatic, or gouty, are produced by this poison.

Carbonic acid possesses the power of decomposing common salt, a fact not generally known, and this becomes a matter of vital importance as far as the maintenance of the integrity of the red blood corpuscles is concerned, as I shall show. That sodium chloride is an indispensable ingredient of the blood in the proportion of one-half of one per cent. is a fact no one will deny. Lower this proportion from any cause and you invite an immediate chemical disintegration of both red and white blood corpuscles. Inject pure spring water into a depleted circulation following a hemorrhage and the patient dies at once, not because the water is toxic but because it dilutes the blood and lowers the vitally necessary per cent. of common salt, thereby disintegrating both the red and white blood corpuscles. Inject under identical circumstances any reasonable amount of normal salt solution and the patient rapidly revives and soon recovers his usual strength. All the normal salts in the blood plasma, including the urates, are held in perfect solution and the kidneys possess no power of selection or rejection of any one of these saline constituents. The urine then is practically a saline mirror of the blood plasma. Uric acid has lately been shown to be a product of the destruction of white blood corpuscles through oxidation of their nuclein. Therefore, either diluting the blood with large quantities of aqueous liquids or lowering the proportion of sodium chloride in the blood in any other way, produces what I shall call a chemical anemia by disintegrating not only the red blood corpuscles, the oxygen carriers, but also the phagocytes, the proved destroyers of disease germs. Naturally we would expect under these circumstances that the uric acid in the urine would be increased.

With these facts before us, and bearing in mind that uric acid never exists uncombined in human blood or tissues, what shall we say of those who advocate drinking large quantities of water "to wash the uric acid out of the blood"? I warn those who advocate drinking large quantities of water, who think pure water can do no harm, that they are extremely likely some day to find themselves victims of nephritis from a chemical or artificially produced anemia as described above; for wherever oxygen and oxygen carriers are de-

ficient, carbon dioxide gas, or rather carbonic acid, increases most abundantly, and the kidneys as well as all the other organs and tissues of the body suffer in consequence. To this carbonic acid or chemical blood destruction must be ascribed the anemia which accompanies rheumatism, pneumonia, scarlet fever, tuberculosis, typhoid fever, etc., the etiology of which has been up to this time a problem of profound mystery to the medical profession. It is a well-known fact that when human blood is deprived of nine-tenths of its oxygen the body dies, and I formulate an aphorism equally true that will stand the test of time: that when any tissue of the body is deprived of nine-tenths of its oxygen it dies or necroses also, since no tissue can be expected to possess a vitality or tenacity of life not enjoyed by the system as a whole. It is in this way and manner that ulcerations of every kind, all local necroses of tissues are produced by carbonic acid saturation of those tissues to the fatal point of oxygen exclusion; and disease germs or bacilli play little or no part in the phenomena.

Anemic persons are very subject to boils. A bruise or other slight injury establishes a local inflammatory condition, a stasis of circulation, the red corpuscles soon part with their oxygen, carbonic acid accumulates, further supply of oxygen is shut out, especially from the central tissues, which necrose in consequence. The *Staphylococcus pyogenes,* nature's chosen scavenger, immediately begins the work of separating the living from the dead flesh, the latter softens, disintegrates, pus forms, and the dead parts exfoliate, after which the resulting ulcer granulates and heals. The germs of suppuration do not cause the death of the central portion or core, which is the popular explanation; deprivation of oxygen is the real cause thereof. If you tie the arteries supplying a given part, deprivation of oxygen causes speedy death of that tissue, which softens, degenerates and exfoliates, ulcerates and heals as before. Staphylococci, as in the previous case, are present and are active in separating the living from the dead flesh, but they did not cause the pathological condition. Press a metal ring upon the skin, hard enough to shut off the circulation for a few hours, and death of the part enclosed occurs from deprivation of oxygen as in the previous case, with suppuration and healing by granulation. No sensible man would say that germs produced this condition.

Carbon dioxide gas resulting from starchy food fermentation and abnormally accumulating in the bowels causes gastric and enteric catarrh, the gases surrounding the feces greatly distending the ascending colon above, as well as the appendix. The feces we know normally are moved onward by vermicular motion and contraction of the intestines, but in cases of overdistention, the frictional hold upon the feces is lost, the upper portion of the colon dilates, the fecal mass falls, and pressing steadily against the ileocecal valve, causes ulceration, which is finally healed by granulation. This scar tissue cuts off from one-third to one-half of the normal circulation of the appendix. A fresh attack of acute indigestion with fermentation and severe pain now ensues; inordinate dilation and saturation of the stomach, bowels, and the appendix also, by these poisonous gases results. The blood-vessels are pressed upon and their canals obliterated mechanically by the imprisoned gases, stasis results, oxygen is shut out, and as in cases of strangulated hernia the parts mortify, the dead tissues suppurate, rupture, and peritonitis and death follow as natural consequences. Oxygen starvation, and not disease germs, is indisputably the cause of this deplorable result.

Ulceration of Peyer's patches and the solitary glands, is a common symptom of anemia. It is not therefore a characteristic or pathognomonic symptom of typhoid fever or produced by its bacilli, but doubtless is caused by the anemia alone, which is always a grave, gradually increasing characteristic symptom of typhoidal conditions. In such cases carbonic acid gas and other toxic gases are prone to accumulate in the bowels and especially in the ascending colon, oxygen is crowded out, the ulcerated parts devitalized and dioxygenized necrose and hemorrhages with perforating ulcers ensue. As it has not been shown that typhoid bacilli *per se* ever cause these perforating ulcers, they are doubtless as in the other illustrative cases caused by a local toxemia and a deprivation of oxygen, without which no tissue can live. This theory of mine is borne out by the uniform experience that fatal cases of typhoidal hemorrhage and intestinal perforation are always preceded and accompanied by great tympanites. The same gaseous distension also occurs in appendicitis before necrosis of the appendix, as every surgeon must bear witness.

Why perforating ulcers of the small intestine should follow extensive burns over the abdomen has been a puzzle to medical men for centuries, but it is easily and scientifically explained by this law of oxygen exclusion by carbonic acid gas. Burns which destroy the skin over the abdomen destroy at the same time its exhaling function. The blood in the subcutaneous tissues, and in the cavity of the abdomen also, becomes saturated with retained carbonic acid, and oxygen is excluded. Perforating ulcers due to necroses of the small intestine follow and death speedily results as in typhoid. If my statements be correct, appendical necroses and perforating ulcers might be prevented by aerating the colon with oxygen or air through a double, high, rectal tube by means of a foot pump and by aerating the peritoneal cavity through a double chambered trocar. The same methods could be utilized in threatened perforating duodenal ulcerations following extensive burns over the abdomen. Certainly these methods are justifiable and much safer than to wait for perforation and laparotomy or death.

Suppose you have a case of pneumonia which does not resolve or clear up. The catarrhal mucus in the bronchial tubes acts as an impervious membrane—a baneful barrier to the entrance of oxygen—and prevents also the exhalation of carbonic acid gas. This gas being retained in the system attacks the common salt in the blood plasma, in the blood corpuscles, and in every tissue and cell throughout the body. A chemical anemia is thus produced. The red blood disks become greatly lessened in number, oxygenation of tissue of course diminishes correspondingly, the pneumonic portion of the lung suffering most from lack of oxygen. Carbonic acid saturation to the point of oxygen exclusion results. Because of this oxygen exclusion the parts necrose as in the other cases, separation of the living from the dead tissues takes place, the necrosed parts break down, soften, and suppurate: a violent fit of coughing is often followed by a hemorrhage and death. The verdict usually is "Tuberculosis of the lungs with hemorrhage." I think a truer diagnosis would be "Carbonic acid saturation of pneumonic lung tissue, excluding

vital oxygen, necrosis resulting." Gangrene of the lung is without doubt due to the same causation, as well as empyema.

What is known as "shock" is supposed to mark the advent of intestinal perforation and peritonitis in typhoid fever. This is not so. Shock is produced by a carbonic acid toxemia through intestinal absorption, or through failure of the skin to perform its functions, and the symptoms which mark this condition may and often do occur without either perforation or peritonitis from hemorrhage, bad news, traumatism, extensive burns over extremities, etc. It should be remembered that all cases of shock are accompanied by a blanched, anemic skin, which means the suspension of its exhaling function and consequently blood poisoning from retention of carbonic acid. The skin cannot be expected to exhale poisons from blood not circulating through it. Whether the result of shock is fatal or not depends on the speedy resumption of the skin exhaling function.

The skin is a vitally important excretory organ of the body, but is not properly understood or appreciated. Its functional activity depends in direct ratio to its supply of blood from which the toxic gases of combustion are exhaled or eliminated.

Almost all acute and many chronic inflammatory diseases are caused by suspension, either local or general, of skin functional activities. Colds start the pathological processes, bronchial catarrhal secretions mechanically prevent CO_2 exhalation as well as the complementary oxidation of red blood disks.

Weak hearts antagonized by fifteen pounds to the square inch of atmospheric pressure result in cutaneous anemia and consequent loss of the skin as a gas-exhaling, blood-purifying organ, and this explains why tuberculous patients improve in high altitudes where atmospheric pressure is lessened. Thus the skin, relieved of undue pressure, regains its normal circulation and functional activity as a blood purifier.

Every physician recognizes the excellent results following dry cupping in pleurodynia, pleuritis, pneumonia, tuberculosis, etc., and yet these beneficial results are only explainable by the production of local hyperemia and increased skin exhalation of CO_2 induced by lessened atmospheric pressure. Certainly dry cupping of the skin of the thorax cannot affect distant inflammatory processes, increase or diminish the circulation of the heart and lungs within the closed air-tight cavity of the chest.

Considering all these facts, I propose to treat pneumonia, pleuritis, pleurodynia, tuberculosis, mental and surgical shock, the so-called toxemic condition now known as uremia, acute and chronic nephritis, and puerperal convulsions by lessing cutaneous atmospheric pressure from fifteen to seven and a half or even five pounds pressure if need be, as follows:

I would place such cases in air-tight compartments, leaving only the head and neck exposed. By means of an air pump and a vacuum gauge any degree of atmospheric pressure within the compartment may be continuously maintained, thus securing a general cutaneous hyperemia with perfect restoration of the skin to its normal functions.

It would be advisable also to strengthen the heart's action by administering strychnine hyperdermically as needed, especially in shock cases.

By this treatment tuberculous patients now senteneed to banishment in high mountainous regions might live at home among friends enjoying also the advantages of the much lauded outdoor treatment at present so much in vogue.

I believe dry gangrene of a limb might be successfully treated in this way. It is worth a trial at least.

We hear a great deal of heart failure in these days, from causes unknown, or from "acute indigestion," and nobody seems to account for it scientifically or give a cause for apoplexy with which it often seems closely associated. Let me give my explanation and the history of an illustrative case. The hemoglobin of the red blood corpuscles possesses a tremendous affinity or attraction for oxygen; I have found an air pump that will raise a column of mercury 29 11-16 inches, quite incapable of separating these elements the one from the other. The tissues or hydrocarbon elements rob the hemoglobin of its oxygen with great facility. It is natural that this should be so, for oxygenation of the body tissues would be impossible without it. Saturating the red blood disks is another element, water, which possesses a great affinity for carbon dioxide gas. It holds 100 per cent. in the open air, 200 per cent. under a pressure of fifteen pounds more, and 1,000 per cent. under a pressure of ten atmospheres. It is this element which shuts out oxygen from the red blood corpuscles as in other tissues and so often produces death from heart failure. Let me illustrate. Two gases cannot occupy the same available space within the red blood corpuscle at the same time. When the red disk returns to the lungs robbed of its oxygen and loaded with carbonic acid from the tissues and blood plasma, the latter is forced out by the oxygen by reason of its superior affinity for hemoglobin. When, however, under increased blood pressure, the water of the red corpuscle contains a sufficient amount of compressed carbonic acid gas to equal or offset the affinity or attraction of hemoglobin for oxygen, the carbonic acid remains in possession of the citadels of life, oxygen is shut out, and the heart muscle, poisoned by the deadly gas, stops beating and the victim instantly falls dead. I believe, however, that many of these cases could be revived by forcing a stream of oxygen into the pericardium as a heart stimulant.

We sometimes hear of two varieties of angina pectoris, "false" and "true." We are told that if a patient survived an attack, he suffered from false angina, but if he succumbed it was equally good evidence that "true" angina was the cause of his demise. There is no "false" angina pectoris. All the symptoms of these cases are caused by carbonic acid toxemia. The danger grows with the degree of blood saturation and culminates in death when oxygen is excluded from the red blood disks as before illustrated.

I have found to my own satisfaction that rheumatism and nephritis, acute and chronic, are caused by carbonic acid poisoning, and valvular heart disease and endocarditis as well. I believe that the dangers attendant on etherization are due to the manner of administering the anesthetic, forcing patients to inhale air poisoned with carbonic acid, and hence nephritis is produced. I can aggravate or ameliorate attacks of muscular or arthritic rheumatism by the use of liquids at meals and after, or refraining therefrom, and also by taking fermented wine, beer, or champagne, or by the use of vinegar on foods, or abstaining therefrom. The ferments in these liquids ferment all the saccharine substances in the blood and tissues and greatly increase the amount of carbonic acid in the system. Carbonic acid also produces inflammation and destruction of the peridental membrane. The rough, sand paper condition of roots of teeth and what was formerly

known as Riggs' disease—now pyorrhea—are really deposits of carbonate of lime, the carbonic acid forming chemical union with vegetable lime salts in the blood. These carbonates of lime are deposited in cartilaginous tissues everywhere. It is in this way that arteriosclerosis and calcareous degeneration of joints, cartilages, arteries, aorta, and cardiac vessels and valves are produced.

We all know the liability of endocarditis occurring in inflammatory rheumatism, and that kidney disease is apt to coexist, but the cause of ulcerative endocarditis has thus far remained an unexplained phenomenon. It is, however, due to the same toxic principle, the local necroses being produced as in all other cases by carbonic acid saturation of the endocardial membrane to the fatal degree of oxygen exclusion. Of course all these cases are fatal, for a saturation sufficient to produce local necroses would paralyze the heart muscle at the same time.

In scarlet fever the pores of the inflamed skin are partially occluded mechanically, interfering materially with the exhalation of carbonic acid which is as I have stated the only poisonous principle in perspiration. A chill completes the occlusion and general systemic poisoning results. Acute nephritis with suppression of urine, edema and general anasarca follow at once and end with what are known as "uremic" convulsions. This edematous or anasarcous condition of the tissues is not due to hydremia alone. Hydremia will not account for all the attendant physical phenomena. The swelling is largely due to carbonic acid gas. Press the finger upon the swollen skin and a pit remains. The water is displaced laterally in the direction of least resistance while the gases being lighter than water, assume the highest possible places beneath the skin. Were this edema due to water alone the pitting would be obliterated speedily as if pressure were made on a rubber bag filled with water.

The subject of metastasis in cutaneous eruptive diseases has long been enveloped in mystery. Why suppression of an eruption should be followed by dangerous inflammatory conditions of distant organs, serous membranes, and other tissues has never been satisfactorily explained. The profession has simply been satisfied to record certain pathological facts without attempting a suitable explanation thereof. Now these things are easily explained. The metastasis of scarlet fever eruptions results in acute nephritis, general anasarca, and convulsions, and was supposed heretofore to be due to uremic poisoning. Better call it carbonic acid toxemia, as this poison is quite capable of producing all the phenomena exhibited.

The vertigo of a champagne drunk lasts four days. It is due to the toxic gases, not to the alcohol it contains. The vertigo of indigestion and that of approaching apoplexy are similarly produced.

I claim that soft cataract of infants following convulsions accompanying intestinal distention and fermentation are due to carbonic acid saturation of the lens and that hard or senile cataracts also are brought on through loss of teeth and inability to masticate food, while senile atrophy of the skin and consequent loss of exhaling function of H_3CO_3 plays an important part in systemic blood poisoning, resulting not only in change of lenticular nutrition but producing the lameness and stiffness which mark the senile condition.

Loss of consciousness in epilepsy, in apoplexy, in the fits or convulsions of children, with internal distention and fermentation, in puerperal eclampsia, and in the so-called uremic convulsions, is produced by carbonic acid poisoning, which paralyzes the center of consciousness of the brain.* That carbonic acid does produce such paralysis almost instantly is proved by the experience of cleaners of old wells who fall unconscious as soon as the head dips beneath the surface of the fatal vapor which is almost pure carbonic acid.

I was lately called to attend Mr. W., aged seventy-four years, a victim of intestinal indigestion who had suffered two years before from a slight apoplexy resulting in paralysis of the left internal rectus muscle. He recovered from this, however, after a few weeks. I found this condition: Divergent strabismus, the pupils dilated irregularly, the patient dazed, unable to collect his thoughts or speak intelligently, great vertigo. Diagnosis: Threatened apoplexy from carbonic acid toxemia through intestinal absorption. I ordered immediately, free catharsis and large rectal and colonic enemata. Before this was accomplished, however, the patient fell in convulsions. Another physician called in recognized imminent heart failure and gave 1-30 of a grain of strychnine subcutaneously with marked benefit. On returning later I ordered profuse enemas which speedily resulted in great evacuations of feces and foul gases. This was followed by an immediate return to consciousness, no paralysis resulting. Had the brain saturation gone on to oxygen exclusion a local necrosis with blood extravasation would doubtless have resulted. Extravasation and paralysis are almost always produced in this manner in my opinion, though in arterial degenerative conditions, rupture may at any time occur, paralysis following blood extravasations. Feeling certain that carbonic acid saturation of the intestinal ulcers to the point of oxygen exclusion is the cause of the perforation of Peyer's patches, hemorrhage, peritonitis, and death, I now treat all cases of typhoid fever by giving sodium chloride 20 grs., water (hot preferred) 8 oz. every two hours with high enemata of normal salt solution every three hours. I keep the bowels open once or twice daily, allowing only a peptonized milk diet, and my patients speedily recover with red cheeks while the fever rapidly diminishes and disappears inside of six days. My theory is that the carbonic acid attacks the common salt forming an innocuous salt carbonate of sodium, that chemical anemia is thereby prevented as well as local poisoning which perhaps would otherwise result in necroses with perforation, hemorrhage, peritonitis, and death. I hope my experience will be duplicated by others and many valuable human lives will be saved thereby.

It is a well-known fact that prolapse of the kidneys produces albuminuria and dangerous nephritis, and the reason is plain. The prolapse twists the blood-vessels, producing venous congestion and stasis of circulation, resulting in a carbonic acid toxemia of the affected kidney with albuminuria. Replacing the kidney by Edebohl's operation restores the normal circulation and the toxemic condition and albuminuria vanishes.

The skin and mucous membranes of stomach and bowels are organs complementary to each

*The "lenticular nucleus" is believed now to be the center of consciousness of the brain. In poisoning by illuminating gas (carbon monoxide), with permanent loss of consciousness, this body is found on post-mortem examination to be destroyed. In the light of my claim that loss of consciousness in epilepsy, apoplexy, uremic convulsions, etc., is produced by carbon-dioxide toxemia, the above facts are extremely interesting.

other. Suspension of the exhaling function of the skin from nervous shock is followed by a great increase of intestinal gases. This accounts for what is known as nervous indigestion. If carbonic acid toxemia can produce an inflammation of the pleura, endocardium, and other serous membranes, is it not equally reasonable to believe it capable of producing peritonitis and cerebral or spinal meningitis?

I am more than satisfied that carbonic acid toxemia will yet be found to be the main factor in the production of cancer of the breast, stomach, and of the intestines, of bronchial asthma, of heart failure in pneumonia, and of cellulitis, gangrene, etc. Having thus found most reasonably that anemia with carbonic acid toxemia resulting in oxygen exclusion is the primary cause of many of the diseases with which mankind is afflicted, I close with this reasonable query, If God in His infinite wisdom has provided four distinct and vitally important organs for eliminating from the human body this excretory, deadly poisonous gas, why in the name of reason and common sense should intelligent physicians, ignoring *His* wisdom, strive to force this gas back into the circulation of their patients—a poison more deadly than strychnine, which unites with no tissue, aids or assists no organic function, but on the contrary shuts out vital oxygen and produces more destruction of human life than any other factor in the universe?

ADDRESS OF THE PRESIDENT AT THE TWENTY-EIGHTH MEETING OF THE AMERICAN LARYNGOLOGICAL ASSOCIATION AT NIAGARA FALLS.*

By J. W. GLEITSMANN, M.D.,

NEW YORK.

Fellows of the American Laryngological Association:

It gives me great pleasure to welcome you here to this beautiful city, so near to the place, the memory of which is dear to us all by the organization of our Association the third of June, 1878, at Buffalo. Of the twenty-one gentlemen addressed the tenth of May, 1878, by the late Dr. Frank H. Davis, we are happy to count ten yet as active members. We can also justly be proud that ours is the oldest national association of Laryngologists in existence.

My personal connection with Laryngology carries me far back to the years 1867 and 1868, when I spent two summers in Vienna and took courses with Leopold von Schroetter, who will celebrate his seventieth birthday next year. Schroetter's dexterity and his patience and perseverance in training the larynx for introduction of instruments excited the admiration of all his scholars. On one occasion I saw him inject sesquichloride of iron into a tracheal tumor with good results.

Those of us who practised Laryngology and Rhinology before 1884, the year of the discovery of cocaine, will fully appreciate the difficulties previously encountered, and the progress made in our specialty since that time.

To the advancement of our science the members of our Association have contributed their full share, and in addition to publications scattered in the medical journals, our transactions are an ever-living testimony of their efficient work and labor. The most valuable and potent incentive for this incessant progressive study is, in my opinion, the fact that the members of our Association with very few exceptions are or have been connected at one time of their life with medical schools in the capacity of teachers, and have been found true to our motto "Docendo discimus."

It is but a natural aim and our first duty to advance science, and by doing so to advance ourselves. There is ample evidence that the members of our Association have conscientiously lived up to this principle, and I have no fear on that score for the future. But besides the scientific efforts and the struggles in daily life, there is in my opinion a feature which we, as members of the oldest and representative American association, should not lose sight of, and this is the endeavor to maintain the standard of Laryngology on a par with other specialties, and to have full recognition and representation in medical colleges and congresses.

The rapid development and progress of Laryngology during the fifty years of its existence and the faithful, energetic work of laryngologists in all parts of the world, have made Laryngology and its allied branches a compact science, which cannot be disregarded and must be known in the fundamental principles to the accomplished clinician of the present time. Being progressive in the true scientific sense, improving its methods and enlarging its fields, Laryngology is entitled to be accorded the same position as held by other corresponding specialties.

You will be requested to take cognizance of and to act upon a letter our Secretary received a few months ago from the Laryngological Association of Vienna, inviting the laryngologists of the world to celebrate, in 1898, the fiftieth anniversary of the establishment of clinical Laryngology by Tuerck and Czermark. In conjunction with this festival it is intended to organize an International Laryngological Congress. You are asked not only to send delegates to the celebration, but also to express your views if the formation of such a congress is desirable and to the interest of our specialty.

The congress can be created only when the preponderant majority of laryngological societies are in favor of its inauguration. As the majority of societies hold only annual meetings, quite a number of replies have not been received yet, but, according to recent letters of Professor Chiari to your President, thirteen societies have expressed their formal consent, one of which, and the only one in the United States so far, is the American Academy of Ophthalmology and Otolaryngology. In addition a large number of other societies have declared their approval, and many prominent laryngologists of different countries have promised their appearance.

The reason for such a movement is not far to seek, and is obvious to one who has followed the history of the International Medical Congresses. At the fifteen congresses held, Laryngology was allowed the privilege of a separate, full section only four times, viz., at Copenhagen, Berlin, Rome, and Paris. At other meetings, as a rule, Otology and Laryngology formed one section, divided into two subsections, but it was left to the Lisbon Committee to add a third subsection on a par with the other two, viz., Stomatology. The controversy about this arbitrary proceeding was carried on with a good deal of feeling in several quarters, and the action of the Lisbon Committee, as well as the futile, urgent demands made repeatedly to the different committees of organization to accord to Laryngology the position it is entitled to, were the real factors for the proposed inauguration of an International Laryngological Congress. The cause of these unpleasant features lies in the deficient organization of the International Congresses themselves. The local Committee of the Meeting-place has arbitrary power, can amalgamate

*Delivered May 31, 1906.

sections or form new ones as it chooses, which at the last six congresses ranged from 16 to 23 in number; it selects the speakers on the subjects for general discussion, the honorary presidents, and against its decisions no direct redress can be had by aggrieved parties. To prevent such occurrences, if possible, in the future, two communications were sent simultaneously but independently of each other to Dr. Semon in London last fall, one by Professor Posner of Berlin, the other by your President. The former one, published in the *Berliner klinische Wochenschrift* September 4, reached the editor of the *Internationales Centralblatt* in time for reproduction and editorial remarks in its October issue, whilst the latter was delayed in transmission and with my consent suppressed, as I preferred not to have my propositions published as a belated communication. Professor Posner's and my own views coincided in the principal points, viz., to curtail the power of the local Committee of Organization and to transfer the same to the national committees and the delegates to the congresses.

The position of Laryngology in medical colleges and universities is more gratifying in the United States than abroad, however much remains to be desired. As it was impossible to obtain catalogues from all colleges, the majority of data was taken from Minerva of 1905, which furnished also the information about foreign colleges. In twenty-nine colleges of the United States having the largest number of students, Laryngology was taught by fourteen professors in ordinary, in two by so-called special professors, in another two by professors residing elsewhere; clinical professors taught in eight, lecturers in two colleges; in the remaining six there was no teacher of Laryngology.

If we compare with these data briefly the conditions on the Continent, we find that B. Fraenkel's assertion in the *Internationales Centralblatt,* July, 1905, is still true, viz., "We have not yet a regular professorship for Laryngology." The majority of teachers in the twenty German, the nine Austrian, and the five Swiss universities are so-called extraordinary professors, with the exception of Rostock and Brussels, where Laryngology, combined with Otology, is taught by a full professor. But if we consider that in six of our colleges mentioned above Laryngology has no representative at all, and that in one of our best ones it is taught by instructors, we have sufficient reason not to remain idle, but to endeavor to elevate our specialty to the standard it deserves.

Permit me now to draw your attention to a few subjects which are nearer to our heart.

We have to be grateful that our ranks have not been broken by the All-destroyer during the past year. Although we have lost no active or corresponding fellow, one of our former active members has died, and I think it is due to his long-standing membership and his frequent attendance at our meetings that his death should not pass unnoticed by us.

Carl Seiler was 56 years of age when he died, in Scranton, Pa., October 10, 1905. He was one of the founders of this Association and remained on the list of active members till 1903. Dr. Solis-Cohen kindly informed me that Seiler's mother was a former assistant of Helmholtz in his famous experiments on acoustics, and an accomplished singing teacher. Dr. Seiler, after graduating in Switzerland, joined his mother in Philadelphia, studied under Dr. Cohen, and became his assistant. Going abroad for further study, he took up also Pathology, and after his return became soon recognized as one of the best pathologists in Philadelphia. He founded the Union Dispensary and was President of the Pathological and of the German Medical Society. His Handbook on Diseases of the Nose and Throat was published in 1879, and the three subsequent editions testify to its popularity and the faithful work of its author.

Although he was never connected with our Association, by the death of Professor Schech of Munich last year Laryngology has lost one of its best men, whose model text-books will secure him a permanent place in its history.

The harmonious meetings of the Council and the efficient work of our Secretary are entitled to the fullest credit in the management of our affairs, and I can only add my words of praise to those of my predecessor, Dr. Rice, especially as to our Secretary, whose labor can only be appreciated when working with him in the preparation for our annual meeting. The affiliations of a number of our members with other societies, and the twenty-year clause, to which Dr. Bryan has already drawn your attention, make his task more difficult than before. Although always some of the best papers are presented by the older members, with the yearly increasing number of members exempt from the obligation of reading papers or coming to our meetings we are not assured of their continuous cooperation, and before long you will in my opinion be obliged to give this matter your earnest consideration.

In conclusion, permit me to indicate a few lines which in my opinion will yield a worthy and fruitful field for future work and investigation.

The technique of examining the upper air-passages has reached a high degree of perfection and has found its fitting climax in Bronchoscopy, whose possibilities seem not to be exhausted yet.

Physiology and Pathology claim our foremost attention and their problems have to be solved by clinical observation as well as by experimental and biological researches. Although many and excellent contributions to the neurology of the larynx have appeared in recent times, the ultimate cause of the proclivity of the abductors to paralysis has not been definitely ascertained yet. Our former member, Donaldson, Jr., and the late Hooper, have discovered the differential influence of certain irritations on the recurrent, and it seems at present that not so much anatomical conditions as investigations of the chemical and biological differences will solve the question.

To the study of the etiology of diseases of the mucous membranes, the manner of entrance of bacilli, Dr. Rice drew your attention last year. Our member, Jonathan Wright, has been making extensive investigations of this subject for some time.

The improved technique has also facilitated diagnosis in many directions, and especially the Roentgen rays are often indispensable and are very useful in accessory-sinus disease. Their more frequent use cannot be too highly recommended to the rhinologist and laryngologist. We are glad to have a paper and demonstration on this subject by Dr. Coakley on our program.

We have made great progress in our therapeutics, in the medical as well as surgical line, in recent years. But our desire to effect a cure is not gratified yet, for instance in the severe forms of parenchymatous infections of the pharynx, in cancer, in tuberculosis. In surgery our accomplishments have found full recognition in all quarters, and there exists a praiseworthy zeal to improve on the old, or to devise new methods. One suggestion I would venture to make, viz., that laryngotomy be more frequently resorted to in suitable cases and be carried out by the laryngologist instead of the surgeon. In the practice

of the large number of members of our Association cases of laryngeal neoplasms, of subglottic tumors will occur, which cannot be removed endolaryngeally, and it is certainly a source of greater satisfaction to relieve a patient by our own action than to turn him over to the surgeon.

I hope that the subject for general discussion, "Diseases of the Trachea," will act as a stimulus to cultivate this field more energetically than heretofore, as it opens new and brilliant prospects for successful work.

The honor you have conferred upon me by electing me your presiding officer is in my opinion the highest a laryngologist can attain. Allow me to express to you my keen sense of appreciation and the hope that I shall be found worthy of your confidence.

A CASE OF PAPILLOMA OF THE LARYNX IN A CHILD.*

By FORBES R. McCREERY, M.D.,

NEW YORK.

M. F., female, two and one-half years old, was brought to my office August 11, 1905. The mother stated that the child had always seemed to have "something wrong with its throat." For six weeks it had suffered from cough and difficulty in breathing. Three weeks before, tonsils and adenoids had been removed at the Cornell Clinic without relief. In fact, the child was growing steadily worse.

The dyspnea and stridor were very marked. Although I was upstairs, the noisy respiration was heard distinctly as she was brought into the house. The supra- and infraclavicular spaces and the sides of the chest sank in deeply with each inspiration. No membrane was visible in the throat. Culture reported next day to be negative. The epiglottis was pinched up and curled over. For this reason, and because of the child's resistance I could not see into the larynx.

As the diagnosis was not clear, I gave some simple croup mixture and sent the child home. The next day she was brought back worse. I succeeded in getting a fleeting glimpse of one vocal cord, which seemed normal. Tilting of the mirror prevented my seeing the other, but I felt sure the obstruction was below the cords and was probably a papilloma.

So little air was entering the lungs that the child's condition was critical and might at any time become very dangerous. As the mother urged me to do something, I decided to intubate. This I did at once, with the result of making matters so much worse that I promptly pulled out the tube. After an interval of rest, I intubated again, using a larger tube, with disastrous result. Evidently the tube pushed down the growth, and I had again to withdraw it. These two intubations exhausted the little thing, and I kept her quiet in my waiting room for about half an hour. There was no improvement in the respiration, and as the only means of saving her life, I did a tracheotomy, with immediate and marked relief.

I then sent the child to Mrs. Willson's house, expecting later to split the larynx and remove the growth. Her general condition was so bad, and she had been so exhausted by weeks of dyspnea and by repeated examinations at the clinic and by me, as well as by the various operations that had been done, that I thought it wise to defer further operation for a month or two, so as to allow time for recuperation.

Three days later I left the city on my vacation, leaving the child in charge of Dr. Preston Satterwhite. A few days later she was seen by Dr. Culbert and Dr. Brewer, who both agreed with the diagnosis and thought it wiser to defer further operation for a few weeks. On returning to the city September 30, I found the child well and happy, breathing nicely through the tube, but quite unable to breathe without it. On withdrawing the inner tube and closing the outer one with my finger, hardly any air passed through the fenestra of the outer tube and the larynx. She could, however, whisper a little. Mrs. Willson's care had added several pounds to her weight. Attempts on my part to examine her larynx caused such loss of appetite and failure of her general health as to lead me to abandon them.

On looking up the statistics of laryngotomy in such cases, I found only 36 per cent. of permanent cures. The great majority of cases promptly recur. I therefore concluded to do nothing further for the present, and the child was taken home.

On February 14 she was again brought to my office. She had increased in weight from 21 pounds in November to 27 pounds. Her general health had been excellent. She could whisper a little better than in November.

On April 23 I replaced the tube by a fenestrated one, but found the child unable to breathe through fenestra and larynx, and hence inferred that the growth was still present.

According to the article in von Bergmann's "System," papilloma of the larynx in children is not infrequently congenital. It is then usually of the multiple, diffuse, cauliflower variety. They grow rapidly, and speedily recur after removal. This tendency to recur diminishes from year to year. Rosenberg's statistics up to 1896 of 109 children on whom laryngotomy had been done 143 times, showed 40 cured, 43 recurred repeatedly, and 20 died, mostly from recurrence and suffocation. Eleven of these children were operated on twice, 3 three times, and 1 seventeen times. Fifty-two were under four years of age. Percentage of cures, therefore, is 36. Eighty-eight children, of whom 13 were under four years of age, were operated on by endolaryngeal methods; of these 40 were cured. Percentage of cures, 45. Three died, and 16 were relieved. The results of endolaryngeal treatment, though very bad, are, therefore, better than those of laryngotomy.

The statistics of another series of 127 cases quoted from von Bergmann's "System" are as follows: No operation, 48 cases, 32 of whom died, 28 from suffocation, and 3 recovered spontaneously. Tracheotomized, 26 cases, 7 of whom died from the operation. Laryngotomized, 21 cases, 8 of whom were cured. Intralaryngeal methods, 40 cases, 13 of whom were cured.

This series gives about the same percentages of cures by laryngotomy as the previous series.

Clark of Boston reported 14 cases in children under fourteen years, these being all the cases treated in the Massachusetts General Hospital from 1889 to 1904, and being about 1 in 1,000 of children under fourteen. Of these 14 cases, 1 was cured, 5 died, 5 recurred, and 3 disappeared from view. Tracheotomy was done on 2, and both died. Laryngotomy on 1, result unknown. Intralaryngeal treatment on 11. One was cured, 3 died, 2 disappeared from observation, and 5 recurred.

*Read before the Section on Laryngology of the New York Academy of Medicine, April 25, 1906.

He advises tracheotomy if needed, and absolute noninterference till the period of active growth is past.

Dickerman of Chicago reports 5 cases. On one, tracheotomy was done, followed by laryngotomy, with recurrence and a second tracheotomy. One had tracheotomy and repeated endolaryngeal operations with final cure, one was still wearing the tube, one died before tracheotomy could be done, and one was operated on five times through the larynx with recurrences but ultimate cure. He advises endolaryngeal treatment, with thyrotomy as a last resort.

J. E. Summers, Jr., reports 3 cases. One had laryngotomy twice with recurrence each time, then wore a tube two years, and recovered spontaneously. Two cases recovered after tracheotomy. He advises tracheotomy only.

Hunter McKenzie reports 7 cases with tracheotomy alone. Four recovered, 1 died a year and a half after the removal of the cannula, 1 disappeared from view, and 1 was still wearing the tube. He reports 13 cases by other men resulting in cure. In 9 of these tracheotomy had been done without further treatment. In one case the tube was worn for five years.

I have spent a great deal of time in reading the reports of these cases, but I will not weary you with further details. The detailed reports of intralaryngeal operations, as given especially in many of the German journals, is sad and discouraging reading. Scores of operations extending over months and years are reported for individual cases. Hunter McKenzie mentions one case that had more than 220 endolaryngeal operations. I confess myself quite unwilling to attempt or advise such treatment in the case of this little girl. Her terror and distress are too pitiable. Laryngotomy gives too bad results. I therefore turn to the alternative of having her wear the cannula for an indefinite period, or until the period of active growth has passed. Then, if necessary, either method of operation may be tried, with better prospect of success than now.

I am well aware of the possibility of cicatricial stenosis of the trachea, due to ulceration from pressure by the tube. I can only say that in all the scores of case reports I have read, I have not found a single reference to this condition, even when the tube was worn for many years.

Minute Anatomy of the Suprarenal Capsule.—A. Moschini states that our knowledge of the minute anatomy of the suprarenal capsule is very limited. He has made some careful histological researches of which he gives us the results. After fixing the tissues in formalin he used a 1 per cent. solution of silver nitrate, which brought out a system of minute connective tissue fibrils forming a fine rete, especially about the vessels of the gland. The connective tissue is largely represented in the formation of the suprarenal capsule, contrary to what has been observed by other methods of staining. There are also two especial kinds of cells to be found: one very small, with many prolongations, which he believes to be connective tissue cells; the other larger, thin, lamellar in structure, concave or flattened, on the nature of which he does not pronounce positively, but leans to the belief that they are of endothelial nature.—*La Riforma Medica.*

Finsen Light and Roentgen Rays in a Cutaneous Syphilitic Lesion.—F. P. Scobbo describes the treatment by means of the Finsen light and the Roentgen rays of a syphilitic lesion that appeared on the nose and contiguous tissues of the face in a patient who gave no direct history of syphilis. There was no history that would indicate a previous attack of syphilis, except the fact that the patient had had four children born at term and dying within a few days of birth. The lesion began with a small, painful nodule on the left pinna of the nose which increased gradually. It was red, irregular, raised above the surrounding tissues, and covered with a slight crust and purulent secretion. The glands in the neck were slightly enlarged. Finsen light was first used, forty-six applications being made on alternate days, and later at longer intervals. The growth would disappear over the original site and increase on some nearby area, never healing entirely. Recognizing that the Finsen rays were not effecting a cure the Roentgen rays were tried, fifty-two applications being made. The result was the same as in the previous treatment. The case was then submitted to mercurial treatment by injections of corrosive sublimate, with immediate benefit, and complete cure after eight injections, no infiltration remaining behind. The light and *x*-ray treatments not only did no good, but seemed to hasten the spread of the lesion. The effects are quite different from those obtained in lupus.—*Giornale di Elettricita Medica.*

Ureteral Fistula After Gynecological Operations.—P. Sfameni says that it is considered a disgrace to have an ureteral fistula after a gynecological operation, and hence such cases are seldom reported. He believes that such fistulæ may not be the result of carelessness on the part of the operator, but the result of a persistence of the canal of Malpighi-Gärtner. He recites twenty-one cases in which the apparent fistula became cured spontaneously, and these he believes not to have been true ureteral fistulæ. In case of a cut ureter the urine should begin to flow through the fistula immediately after operation, whereas these cases showed the flow sometimes from two to thirty-nine days after the operation. In only a few cases was there an examination of the fluid, and in these it was found that it did not resemble the urine drawn from the bladder of the patient; it had a lower specific gravity, and contained no urea. The canal of Malpighi-Gärtner is the excretory duct of the Wolffian body, the primitive kidney. If this persisted in the adult, fluid might escape from this excretory duct as a result of the stimulation of the tissues at the healing of the operation. The orifice of the duct varies in its location, in some instances being quite near the vulva. The secretion would stop as soon as the irritation ended with the healing of the wound. Pain has been observed and a fluctuating tumor formed when the supposed fistula was closed. The author believes that the cases he reports are cases of persistence of the duct of Malpighi-Gärtner.—*Archivio di Ostetricia e Ginecologia.*

MEDICAL RECORD.

ORIENTALISM.

IN the *Lancet* of June 23 appeared an article with the above title, from the pen of a well-known London ophthalmologist, Mr. H. Work Dodd, describing a clinical condition which would seem to be the result of a new, or at any rate an obscure disease.

The patient in question was a man, aged 47 years, who up to the year 1898, to outward appearance, enjoyed excellent health. He then developed ptosis of the right eyelid, followed shortly by ptosis and external strabismus on the left side. He was successfully operated upon, so far as the right eyelid was concerned, but in the following year was admitted into a hospital complaining of general weakness and vague alterations of sensation. During this time his general appearance was undergoing a change, although on careful examination nothing abnormal could be detected in any organ or system, and he was discharged from the hospital.

The curious phase of this case is that the man during a period of but a few years absolutely changed in appearance. When Mr. Dodd first saw him he was a finely developed, erect man of 5 feet 10¾ inches in height and weighed, without being at all obese, 228 lbs. He was an athlete of prominence and was the beau-ideal of vigorous, masculine, athletic manhood. He had plenty of hair, a long blond mustache, and was fair in appearance. Moreover, he was a cheerful, capable, quick-moving and intelligent man. At the present time he is smaller, stoops, is only 5 feet 8 inches in height, weighs 165 pounds, is weak, his hair has changed to mouse color, his mustache cannot grow hairs longer than a quarter of an inch and they are soft and sparse, his chin never needs a razor, his complexion is sallow, and his whole aspect is darker than before. In fact, his appearance has altered so completely that his fellow workmen have christened him "the Japanee." The man's mental characteristics seem to have altered quite as much as has his physical aspect. From being a hustling, vigorous individual, thoroughly endowed with the verve and go of the Anglo-Saxon race, he has become apathetic to a degree entirely in keeping with his Eastern appearance. He is now of the Tartar or Mongolian type, but saved from being definitely Mongolian in face by the tilt of his eyes, which is not upwards, and by their color, which is a dullish blue. His skin is soft, thin, and delicate like a woman's skin; it is normal in moisture, elasticity, and electrical resistance. The entire body is almost wholly hairless, the nails of the hands are normal, but those of the feet are brittle and broken. The majority of the organs and functions are normal and act normally, but the muscles generally are weak and flabby, especially those of the arms. Knee-jerks are present, equal, and not increased. Sexual desire and power are said to be completely lost. A complete blood examination showed no abnormality. The patient seems always sleepy, and the memory is somewhat defective.

It should be mentioned that the patient contracted syphilis some eighteen years ago, but, as Mr. Dodd points out, it must not be forgotten that the alterations in appearance began only with the obscure illness for which he was treated in 1899. The reporter of the case is driven to the conclusion that possibly changes have taken place in some important elaborating structure, testicular, thyroid, or elsewhere, and he notes that the thyroid gland cannot be felt while the testicles are smaller than usual, unequal in size, abnormally tender and soft, and indeed appear to be atrophied. The author quotes two cases of apparently similar nature, one of which came under his direct notice, and the other has been under the care of Dr. Henry Campbell. In one of these instances there was a doubtful, and in the other a definite, history of syphilis. He also relates the case of a man suffering from diabetes insipidus, who was under his care in hospital, who had the same appearance as the first patient, but he does not know whether any change had taken place, or whether he had been of this curious type originally. He also says that he is certain he has seen other cases of this type in men, but cannot call to mind seeing anything similar in women.

It may be noted as probably more than a coincidence that in the cases mentioned by Mr. Dodd, in which there were definite histories, syphilis had occurred, and therefore it is more or less reasonable to presume that this disease was the originating cause. However, the cases referred to do not seem to fall into any recognized class, and Mr. Dodd's request that others who have had greater opportunities than he has had will bring forward other cases, if complied with, may aid in clearing up what now seems to be a mystery.

THE PREDISPOSITION OF THE PULMONARY APICES TO TUBERCULOUS INFECTION.

BEFORE the bacterial character of tuberculosis was established no serious effort had been made to account for the peculiar liability which the apices of the lungs manifested towards the localization of this process. In accordance with the beliefs current at that time it was conveniently ascribed to a "predisposition," and as there was no way to disprove this assumption, the case rested. With the advance of pathological knowledge, the theory was proposed that a nontuberculous apical bronchitis was the forerunner of the more specific process, but it is now well known that these types of bronchitis are tuberculous in most instances from their inception. The development of bacteriology and the discovery of the tubercle bacillus led to investigations along entirely different lines, and as pulmonary tuberculosis

was assumed to be due to inhalation of the specific germ, the reason for the more frequent apical localization was believed to reside in the fact that the bronchi in the upper lobes of the lung were bifurcated in such a manner that their invasion by the bacillus was particularly easy. Many theories were built up on this basis, but a critical inspection shows that they lack uniformity, for it is now well known that no very constant anatomical differences exist in this respect between the apices and other portions of the lung.

But if we take up the physiological characteristics, decided differences can be made out, according to L. Hofbauer (*Zeitschrift für klinische Medizin*, vol. 59, No. 1), and these exist normally as well as pathologically. In the first place it is known that the function of the upper part of the lung differs from that of the lower. Although primarily concerned with the interchange of gaseous materials, not all portions of the organ are equally involved in the process, and the inferior segments of the lungs are much more completely aërated than the superior, owing to the action of both the intercostal muscles and the diaphragm. In addition to this there is also a lack of uniformity in the intrathoracic pressure as shown by actual experiment, and these two factors together exert a marked influence on the pulmonary circulation of both blood and lymph. According to Hofbauer, the intrathoracic pressure which reaches its maximum degree in the caudal portions of the lungs becomes very greatly lessened the nearer we approach the cranial segments, and in the apices there is very little change. The consequent diminished circulation in these parts interferes with the proper nourishment of the pulmonary parenchyma of this region and reduces the amount of resistance as compared with that in other portions of the lung.

It will be seen that this theory fits very well with any idea as to the manner of infection by the tubercle bacillus which one may be inclined to adopt, whether this be through the medium of the blood, the lymph, or the air, and although purely theoretical it seems confirmed curiously enough by the autopsy findings in a case recently reported by Birch-Hirschfeld. A woman contracted a pulmonary tuberculosis during the early part of her pregnancy and died at term as the result of an anthrax infection. The lower lobes of the lung were the site of an area of recent cheesy degeneration similar to what is ordinarily found in the upper portions of the organ, and the reason why the former was invaded may be traced to the insufficient aëration with its accompanying effect on the circulation of the part, due to the upward pressure of the diaphragm from the enlarged uterus. In other words we have reproduced in the lower an analogous condition to that ordinarily found in the upper lobes, and consequently a *locus minoris resistentiæ*.

"ONE-CHILD STERILITY."

We are not ordinarily accustomed to regard as sterile a union in which pregnancy has occurred once, and yet under certain circumstances the term can be very aptly thus applied. There are numerous instances in which the birth of a single child or possibly only a miscarriage has been succeeded by a condition of absolute sterility which persists throughout the remainder of married life. In the German medical literature there are frequent references to this condition, but among American writers it has hardly received the attention it deserves. Every practitioner is no doubt familiar with instances in which no further conception occurred during several years after the birth of the first child, although such an event may have been greatly desired. The physician is consulted as to whether the power of child bearing can be restored and the patient is usually advised to submit to a divulsion and curettage. Sometimes this is effectual, but more often it fails to produce the desired result. F. S. Mathews, writing in *Surgery, Gynecology, and Obstetrics* for May, 1906, gives the conclusions derived from some studies into the comparative frequency of this condition and its causes. Among one thousand gynecological dispensary cases there were eighty-two instances of "one-child sterility," in which the pregnancy terminated within the first two years after marriage and no further conception took place during the next three or more years. Among this number there were only seventy-five cases of absolute sterility. In one hundred consecutive gynecological cases in private practice, there were eighteen women sterile after three years of married life and fifteen sterile three or more years after one pregnancy.

It may be assumed that in the class of cases under discussion, the sterility is due to some condition in the female rather than in the male genital tract, and that it is not the result of a congenital factor. More likely the cause is something thing that took place during the pregnancy or the puerperium, and Mathews is inclined to lay the blame in the majority of instances to gonorrhea, which may supervene about the same time with pregnancy and is known to spread readily to the tubes. Even puerperal sepsis seems less likely to bring about sterility, as the resulting endometritis or salpingitis is frequently recovered from. Retroversion or flexion and subinvolution furnish another small percentage of cases, but the frequency of gonorrhea shows that in recommending treatment this factor must be carefully borne in mind. As Mathews truly says, it is "foolish to dilate the cervix and curette the uterus when the history points to occluded tubes." In view of the increased attention which the subject of sterility has been accorded by the profession, the variety here referred to is deserving of closer study. This means that more care than ever should be given to the pregnant woman if gonorrheal infection supervenes, and as this can hardly ever be eradicated during pregnancy itself, the treatment should be continued for some time after.

THE VALUE OF THE DIFFERENTIAL LEUCOCYTE COUNT.

The realization that the blood must necessarily come into intimate relation with every inflammatory process, no matter in what part of the body the latter might be situated, has led to the adoption of clinical methods by the aid of which certain changes can be detected in this medium and thus made use of in

the diagnosis of surgical conditions. An increase in the number of the white blood cells was at first taken as a criterion of the progress of hidden purulent processes, but in the course of time it was found that this sign was not always absolute, and the search was continued for some other and more certain evidence. It was then determined that the key to the situation lay in the study and recognition of the changes which took place in the relative number of the polynuclear leucocytes, and the differential blood count and its relation to the total leucocytosis is to-day the most valuable diagnostic and prognostic aid in acute surgical diseases that is furnished by any of the methods of blood examination.

In the practical application of this clinical method, the determination of the disproportion which exists between the leucocytosis and the percentage of polynuclear cells is the determinative factor. In order to have some standard by which this disproportion may be measured, C. L. Gibson (*Annals of Surgery*, April, 1906) proposes the adoption of a chart which may be tentatively recommended under the arbitrary designation of "standard." As a basis for constructing such a chart the resistance of the body against infection has been adopted, although this must be essentially purely an arbitrary factor. Gibson estimates that in inflammations which are well resisted, the polynuclear cells are increased approximately one degree for every thousand of the total leucocytosis above ten thousand. Starting with such a basis experimental charts have been worked out and the results apparently show that such a standard may form a very good working basis for the measurements which have been adopted. Briefly described, the chart is divided into units of one centimeter each. A horizontal base line is drawn as the starting point of the pathological leucocytosis of ten thousand on the left hand side, while the right hand side of the base line corresponds with the index of 75 per cent. polynuclear cells, the limit more or less arbitrarily chosen. Variations in these proportions are noted at the proper level on the polynuclear side of the chart, and the vertical distance between the two points will denote the disproportion between the two counts. Such a chart would seem useful in comparing examinations made from day to day. From computations based on a larger number of observations, some more definite standard may perhaps be adopted, but the main idea as suggested by Gibson is certainly worthy of attention.

Sudden Death Following the Injection of Horse Serum.

One of the serious objections which has been urged against the use of diphtheria antitoxin has been the apparently fatal character of the latter in certain, fortunately isolated and uncommon, instances. The reason for this effect has never been explained, although attempts to seek a cause have been numerous. The latest contribution to the subject is a paper by M. J. Rosenau and J. F. Anderson, in Bulletin No. 26 of the Hygienic Laboratory of the Marine Hospital Service for April, 1906, in which are noted the results of their observations on guinea pigs which have been subjected to treatment with horse-serum. It was found that both the normal and the antitoxic serum was practically harmless for normal guinea pigs, but was poisonous to those animals which had previously been injected with this substance, the period between the two injections being about ten days. The first injection, therefore, seems to render the animal susceptible, and when the second injection is made there follow respiratory embarrassment, paralysis, convulsions, and death. The poisonous principle in horse-serum appears to act upon the respiratory centers, and the heart continues to beat long after the breathing stops. The toxic action here referred to seems to bear no relation to diphtheria, for the guinea pigs cannot be rendered susceptible by previous infection with the *Bacillus diphtheriæ* or by previous injections with diphtheria toxin. The writers are convinced, however, that guinea pigs first injected with diphtheria toxin plus horse-serum are more sensitive to subsequent injections of horse-serum than are guinea pigs sensitized with a first injection of horse-serum alone. Diphtheria antitoxin therefore seems to play no part in this poisonous action, and is itself harmless. In applying the results of their animal experiments to the human species, the explanation offered by the writers is not quite so clear. It seems probable, however, that man may in certain instances be rendered similarly sensitive to the injection of a strange proteid, and that this explanation must be considered as well as the status lymphaticus, which has heretofore been assigned as the cause of sudden death following the injection of horse-serum.

Nursing by the Tuberculous Mother.

Investigations in considerable number have been made with reference to the presence of the tubercle bacillus in the milk of animals, but in only a few instances has the attempt been made to demonstrate the bacillus in the mammary secretion of the human species during the period of lactation. With the idea that this knowledge might prove of value in the etiology of infantile tuberculosis, O. Füster was led to make an investigation which, although not very extensive, afforded results fairly uniform in character. These, as detailed in an article in the *Wiener klinische Wochenschrift*, No. 20, 1906, show quite clearly that in the dissemination of tuberculosis the milk of an infected mother is not apparently an important factor. Füster examined the milk and colostrum in a number of undoubted cases of maternal tuberculosis by microscopic methods and also injected some of the suspected material into guinea pigs. The results were practically negative, and in only two cases were any organic changes noted in the animals and these were too indefinite to warrant their being attributed to a tuberculous process. These observations, together with similar ones made by certain other writers, seem to show that the direct transmission of the disease from mother to infant by this means is quite improbable. What, then, is the danger connected with an infant's nursing a tuberculous mother? The risk, it appears, comes rather from the necessarily intimate contact to which the child is subjected with the infected mother and her environment, and this is what contraindicates breast feeding in such cases. But when the tuberculous process is quiescent, if not actually arrested, in the mother, and the physical and clinical signs show no advancement during pregnancy, and the sputum remains free from tubercle bacilli, then, Füster claims, breast feeding may be continued without exposing the child to the danger of becoming itself tuberculous.

News of the Week.

Public Health and Marine Hospital Service.—An examination of candidates for the position of assistant surgeon in the Public Health and Marine Hospital Service will be held at Washington, D. C., Monday, August 6, 1906. Candidates must be between twenty-two and thirty years of age, graduates of a reputable medical college, and must furnish testimonials from responsible persons as to their professional and moral character. In addition to the physical examination, candidates are required to certify that they believe themselves free from any ailment which would disqualify them for service in any climate. The examinations are chiefly in writing, and begin with a short autobiography of the candidate. The remainder of the written exercise consists in examination on the various branches of medicine, surgery, and hygiene. Successful candidates will be numbered according to their attainments on examination, and will be commissioned in the same order as vacancies occur. Upon appointment the young officers are, as a rule, first assigned to duty at one of the large hospitals, as at Boston, New York, New Orleans, Chicago, or San Francisco. After five years' service, assistant surgeons are entitled to examination for promotion to the grade of passed assistant surgeon. Promotion to the grade of surgeon is made according to seniority, and after due examination as vacancies occur in that grade. Assistant surgeons receive sixteen hundred dollars; passed assistant surgeons, two thousand dollars, and surgeons, twenty-five hundred dollars a year. When quarters are not provided commutation at the rate of thirty, forty, and fifty dollars a month, according to grade, is allowed. All grades above that of assistant surgeon receive longevity pay, ten per centum in addition to the regular salary for every five years' service up to forty per centum after twenty years' service. The tenure of office is permanent. Officers traveling under orders are allowed actual expenses. For further information, the Surgeon-General, Public Health and Marine Hospital Service, Washington, D. C., should be addressed.

Cholera at Manila.—The efficacy of the methods employed by the sanitarians in Manila is shown by the prompt fall in the morbidity since the first outbreak of cholera in that city a short time ago. During the week ending July 4 there were 116 cases and 99 deaths from the disease, but since then the daily number of cases has diminished almost one-half. The victims have been almost entirely among the natives, although several deaths among the white population have been reported. The chief difficulty in controlling the situation consists in the opposition offered by the natives, who fear the health officials and endeavor to conceal cases of the disease.

Yellow Fever at New Orleans.—It is asserted that the case of yellow fever recently reported from New Orleans has proven itself to be typhoid fever. An elaborate system of houseboat quarantine has been established, whereby fruit steamers are enabled to get their cargoes ashore without delay. No members of the sea-going crew are allowed to land at New Orleans, their places being taken by a special unloading crew, which boards the vessel from a houseboat, on which the sea-going crew remain until picked up again on the outward trip. Only the captain of the vessel is allowed to go on shore at New Orleans, and then only during the daytime. The steamers are fumigated with sulphur and pyrethrum four times on each round trip.

Deafness and Blindness in the United States.—A special report on the blind and deaf of the country has been issued by the Census Office under the direction of Dr. Alexander Graham Bell. The total number of blind persons in the United States in 1900 was at least 64,763, of whom 35,645 were totally blind. Of this number 37,054 were males and 27,709 females. The blindness was congenital in about one-tenth of the cases, and developed after the age of twenty years in 65 per cent. The native born whites suffer less from blindness than do negroes and the foreign born. In about 5 per cent. of the cases reported, the parents of the blind were cousins. Of the blind whose parents were so related, 25 per cent. were congenitally blind, while among the blind whose parents were not cousins the proportion of cengenitally blind was only 6.8 per cent. Of the blind at least ten years of age 20 per cent. were engaged in some gainful occupation. Deafness is more common in the northern part of the United States than in the South, and there are more deaf males than females. The total number of deaf is given as 89,287, of whom 37,426 were totally deaf and 51,861 partially deaf. From the latter class, however, are eliminated those merely "hard of hearing." Of the totally deaf 52.5 per cent. were males and 91 per cent. were deaf from childhood (under 20 years of age) and 36 per cent. from birth. Of the 89,287 persons reported as deaf, 55,501 were able to speak well, 9,417 imperfectly, and the remainder not at all.

Tuberculosis in France.—According to a report received a tthe Department of Commerce and Labor, the yearly deaths from tuberculosis in France number 150,000, representing a death rate of 39 per 10,000 inhabitants. The statistics obtained by the French authorities show that the mortality from this cause increases in almost regular proportion to the density of population. In Paris, for example, the ratio of deaths from tuberculosis is 45.2; in cities of 100,000 to 492,000 population, 34.4; in cities of 20,000 to 30,000 inhabitants, 30.8; in cities of 5,000 to 10,000, 23.4, and in cities of 1,000 to 5,000, 20.4. In the course of an inquiry into the effect of various occupations in predisposing to the disease, it was found that those vocations bringing the worker into contact with dust were especially dangerous. Laundry workers were found to be the most seriously affected, however, their mortality from tuberculosis in some regions being 75 per cent. Contact with the soiled linen is supposed to be the reason for this appalling morbidity. It is also stated that 240,000 out of 400,000 bakers in France are tuberculous.

Site for Hospital for Criminal Insane.—The commission appointed by Governor Pennypacker, of Pennsylvania, for the selection of a site and the erection of a State Hospital for the Criminal Insane, has secured from the Delaware and Hudson Railroad Co., as a gift, 450 acres of land at Fairview, high in the mountains of Wayne County. The State Legislature has appropriated $200,000 for the erection of a building, including $10,000 for a site. The new hospital is to have accommodations for from 800 to 1,000 patients, and the total cost will be about $1,000,000.

Vital Statistics of Philadelphia.—As a result of the intense heat, the number of deaths in the city of Philadelphia for the week ended July 7 was the highest in five years, namely 651. Of this number 277 occurred in infants under the age of five years, while 17 were due to sunstroke. Diarrhea and enteritis alone caused one hundred and forty-eight deaths in children under the age of two years, and

nine in children above this age. Pulmonary tuberculosis is charged with fifty-four deaths, Bright's disease with forty-nine, congenital debility with twenty-five (not including fourteen due to marasmus), whooping-cough and heart disease each with twenty-four, apoplexy with twenty-two.

A Sanitary Commission for Madrid.—A hygienic commission has been formed in Madrid for the purpose of instituting radical measures for effecting reforms in the sanitation of the city. Investigation of the slums has revealed conditions in urgent need of amelioration; for example, four hundred and thirty-eight tenement houses were found to be occupied by 52,521 persons, with only one lavatory to each house and only one hand basin to each 100 tenants. Madrid's death rate is 28 per 1,000, and in 1905 3,192 children died under the age of one year.

Examinations for Meat Inspectors.—The Civil Service Commission has announced an examination to be held for the purpose of obtaining sufficient eligibles from which to organize the force of meat inspectors, which was authorized by the Agricultural Appropriation Bill passed by Congress recently. The examination will be held July 21, and the commission hopes to secure an eligibility list of 400. The candidates are not required to be veterinarians, but they must possess some practical experience in the handling of meat and meat products. They must be between 21 and 50 years old. The salaries will range from $1,000 to $3,000, according to the length of service and the experience of the inspectors.

Award Against a Dental Company.—An opinion of the Appellate Court confirms the decision of the Superior Court in a damage suit brought against a dental firm of Los Angeles, Cal. The plaintiff claimed damages because in having seven teeth extracted, after six had been successfully removed, the seventh slipped from the forceps and was drawn into the lung. She was awarded the sum of $2,400.

Fourth of July Casualties.—On July 5 nearly 500 accidents and one death, caused by the Fourth of July celebration, had been reported to the police of Manhattan as occurring in this city alone. Reports from all over the country show a death roll of at least 50, and last year's record of over 2,500 serious injuries will probably be equaled.

Red Cross Conference at Geneva.—The international Red Cross conference which has been held at Geneva, Switzerland, came to a close on July 6, and it is stated that the desired changes in the international Red Cross agreements were made without serious objection by any of the powers taking part.

Dr. J. C. Corbus has resigned as superintendent of the Illinois Eastern Hospital for the Insane at Kankaee, and the resignation was accepted formally by the Board of Trustees July 6, at the regular meeting at that institution. His successor probably will be appointed in a few days. Dr. Corbus has been superintendent of the hospital for nine years, having been appointed by Governor Tanner.

Dr. J. A. Egan, Secretary of the Illinois State Board of Health, has been appointed a member of the American Committee of the Fourteenth International Congress of Hygiene and Demography.

New Hospital in South Chicago.—Plans for a new hospital two stories in height, 64 by 40 feet, and to cost approximately $10,000, have been prepared.

Sanitary Matters on the Isthmus.—If the United States succeeds in making as great an improvement over the French company in the actual digging of the Panama Canal as it has in sanitary matters, some persons now alive may celebrate its opening. The *Mexican Investor* makes the following interesting comparison: In 1882, the second year of French work on the canal, the death rate was 112 per 1,000. In August, 1905, under American sanitary rule, there were but eight deaths among six times as many men, the mortality rate being something less than one death in every thousand, or roughly, twelve per thousand per year, which means that of every thousand men in the canal zone the lives of an even hundred are being saved every year. In August there were about 12,000 men there.—*The Globe.*

Consolidation of Medical Journals in Los Angeles.—Announcement is made that the *California Medical and Surgical Reporter* has purchased the *Los Angeles Medical Journal,* and that the publication of the latter as a separate journal will cease.

West Virginia State Medical Association.—At the thirty-ninth annual meeting of this society held at Webster Springs on June 20 to 22 the following officers were elected: *President,* Dr. William W. Golden, Elkins; *First Vice-President,* Dr. V. T. Churchman, Charleston; *Second Vice-President,* Dr. M. F. Wright, Burlington; *Third Vice-President,* Dr. C. T. Smith, Tunnelton; *Secretary,* Dr. T. W. Moore, Huntington; *Treasurer,* Dr. T. L. Barber, Charleston. *Councillors*: First District, Dr. H. P. Linsz, Wheeling; Second District, Dr. R. H. Powell, Grafton; Third District, Dr. P. A. Haley, Charleston; Fourth District, Dr. W. S. Link, Parkersburg; Fifth District, Dr. C. R. Enslow, Huntington, and Dr. J. W. Preston, Keystone. Huntington was selected for the next place of meeting.

Queens Medical Building in the University grounds, Kingston, Ont., was destroyed by fire on July 4. The fire is supposed to have started from an oil stove. The loss is estimated at nearly $100,000.

Tazewell County (Va.) Medical Association.—At the regular meeting of this society, held at Tazewell on June 28, the following officers were elected: *President,* Dr. Isaac Pierce; *Vice-Presidents,* Drs. George M. Walker and L. J. Stump; *Secretary,* Dr. C. T. St. Clair; *Treasurer,* Dr. W. I. Painter.

Wisconsin State Medical Society.—At the sixtieth annual meeting of the society, held at Milwaukee on June 29, Superior was chosen as the next place of meeting, and the following officers were elected: *President,* Dr. L. H. Pelton, Waupaca; *First Vice-President,* Dr. A. J. Burgess, Milwaukee; *Second Vice-President,* Dr. W. E. Ground, Superior; *Third Vice-President,* Dr. W. J. Pinkerton, Prairie du Chien; *Secretary,* Dr. Charles S. Sheldon, Madison; *Treasurer,* Dr. S. S. Hall, Ripon.

Obituary Notes.—Dr. Palmer C. Cole of this city died suddenly on July 4, at the age of seventy-one years. He was graduated from Harvard Medical College in 1858, and served as surgeon during the Civil War. He was the first president of the New York Harvard Alumni Association.

Dr. G. W. Birch of Stanton, Conn., died on July 4, at the age of sixty-five years.

Dr. Charles Lester Spaulding of Kansas City, died suddenly on June 24 at the age of thirty-seven years. He was a graduate of Williams College and had been practising in Kansas City for some years.

Dr. J. W. Cline of Dayton, O., died on July 3 at the age of seventy-three years. Dr. Cline was long prominent as a practitioner, but retired from active work some years ago.

OUR LONDON LETTER.

(From Our Special Correspondent.)

HOSPITAL SUNDAY—MITRAL STENOSIS IN PREGNANCY—TUBERCULOUS PORK—PRESERVED FOODS—MEDICAL REPORTS—A PARASITOLOGICAL LABORATORY—DRUGS AND FATIGUE—LIVINGSTONE COLLEGE—OBITUARY NOTES.

LONDON, June 22, 1906.

THE week opened with Hospital Sunday. This collection began in 1872, under the presidency of the Lord Mayor, and each year since his successor has acted as president. At St. Paul's the preacher urged the necessity of systematic support, and said year by year the aid of the State seemed to draw nearer. It was not a question of conscience as to how to give alms. It was the moral self-respect of wealthy London that was involved. There was a large congregation at the afternoon service, the Lord Mayor and Sheriffs attending in state, and as it was "judges' Sunday" also, being the first after Trinity, the bench was fully represented.

The Bishop of London preached at Marylebone and said he would deeply regret to see the hospitals put on the rates. It would be a sad day for London, for when contributions were enforced the love of hospital work would go.

It is not possible to estimate the result of the effort at present, as the moneys only reach the Mansion House very slowly. In fact the various persons would do well to forward their collections more promptly than they have been in the habit of doing. There was a good collection among city men and there was an effort to reach those who usually pass the week-end at a distance.

Mitral Stenosis and Pregnancy was the subject of a paper at the Medico-Chirurgical by Drs. H. French and H. T. Hicks. They found that when heart failure developed it was not with the first pregnancy—often only after several. The treatment was not to be modified by the pregnancy. It was not right to forbid marriage to all women who had mitral stenosis. Such a patient, whether married or single, was not likely to reach old age. But after twenty, with good compensation pregnancy was not so likely to accelerate heart failure, as recent text-books stated. Sir D. Duckworth thought marriage unwise. The probability of early breakdown was greater in the poor. The plethora of pregnancy threw an extra strain on the heart. Dr. Herman thought the danger had been exaggerated; with good compensation there was only slight risk, and that about the seventh month. A subsequent speaker advocated rapid delivery (forceps and chloroform) in threatening cases; another held that compensation might in some cases be increased through stenosis.

Dr. Poynter appealed to statistics to show that the frequency of heart disease through rheumatism was the same in the two sexes. He thought that perhaps in pregnancy there was an increase. Dr. Bonney mentioned three cases of malignant endocarditis occurring in puerperal sepsis and a fourth in which a pregnant woman was attacked. Dr. W. S. Griffith said delivery might be accomplished in severe cases of stenosis and yet death occur during the puerperium. The risk, though there, had been exaggerated. In 4,171 recent deliveries in hospital there were 28 cases of heart disease. Of these 2 were aortic and both did well; 12 were mitral stenosis and 1 of them died; 14 were mitral regurgitation and 2 of these died.

Dr. Buchanan's report to the Local Government Board in reference to tuberculosis affecting pigs was issued last week as a Blue-book. It deals with the liability of pigs to tuberculosis, the origin of the pigs sold in London, and the methods of inspection at home and abroad. Dr. Buchanan says that "at present there seems to be no warrant for regarding tuberculous matter derived from the pig as comparatively harmless to man, merely because it comes from the pig. That any person who takes tuberculous matter of animal origin (containing living bacilli, etc.) into the body along with food, thereby incurs some risk of acquiring tuberculous disease is an inference which is generally drawn and rests upon a considerable mass of evidence, experimental and clinical." Dr. Buchanan thinks, however, that it is not possible to form an opinion as to the extent to which meat from tuberculous animals is responsible for the human disease. Relatively to other causes he thinks it is no doubt small.

The Royal Commission of 1898 held that in this country the risk had been exaggerated. The incompleteness and lack of uniformity of measures adopted by our public authorities for preventing the importation or sale of diseased meat has often been exposed. Dr. Buchanan says there would be many advantages in extending the Dutch and Danish system. The question of so dealing with diseased meat as to prohibit its use as food is a delicate one. Dr. Buchanan says suitable treatment (cooking or sterilizing) should enable a large proportion of condemned meat (including that condemned as tuberculous), to be "used as food," although he admits it would have to be sold at a low price. To say the least this is not appetizing reading, and some officers of health have expressed the same view.

Another report attracting attention in reference to imported foods is that of the health officer for the port of London (Dr. Herbert Williams). He says that decomposed food will cause bulging of the tins ("blowing" as it is called) in most cases, but if the liberated gas is not sufficient to cause bulging it requires experience to detect the change. "Blown tins" are apparent to anyone, and when opened the contents are offensive. Another medical officer reports that tin and lead on rare occasions have been detected by chemical examination. The question of diseased meat being employed has attracted the attention of several medical officers of health and it is obvious that the detection of such frauds after the arrival of the tins in this country must be extremely difficult. In fact at present bacteriologists or chemists are alike unable to protect the public, and rigid inspection at the place of canning affords the best security.

The Royal Institute of Public Health inaugurated a parasitological department on Wednesday. Dr. Smith (Mayor of Holborn) presided and said the new departure had been created for research work in tracing diseases which may be transmitted by insects and animals to man. Such work he held would be of immense value. The Institute was founded in 1886 for the purpose of obtaining skilled and trained men for public health positions. The Institute could boast of laboratories equal to any in London, and in view of recent advances in our knowledge of the solution of diseases in animals and man it had been decided to establish this new department. Sir Patrick Manson spoke of the discoveries as to mosquitos and other parasites as transmitters of disease. The old theory was that dirt was the cause of diseases. Now we can show the particular element in the dirt which is responsible. In developing this field of research the institute will do much for medical science and it is only on such lines that disease will be effectually combated.

The Croonian Lectures at the Royal College of Physicians this June were entrusted to Dr. W. H. R. Rivers, who took for his subject the "Action of Drugs on Fatigue." He gave some account of experiments by previous observers before putting forth the results of his own investigations. He pointed out the distinction between the sensation of fatigue and the process of exhaustion. Hard mental work often gives rise to fatigue, and a drug which removes or diminishes that feeling does not necessarily relieve exhaustion. After a dose of caffeine there is an increase in the force of muscular contractions lasting for about an hour. In 1893 kola was held up as a remedy for fatigue, and there seemed to be an increase in the amount of work that could easily be done under its influence.

Caffeine is a stimulant of the nervous centers rather than of muscles, and after the initial increase is followed by a lowering of activity, as the essential oils in tea also do. Indeed one observer concludes that these drugs are in reality acceleratives of fatigue, reducing the total output of work, although they produce a temporary relief or exhileration. Tea causes an immediate but brief increase of the working capacity. As fatigue increases there is also an increased output of central energy, and this has to be reckoned with. So, too, have psychical influences such as interest in an experiment. Training is necessary before undertaking experiments. He had himself given up tea and coffee in order to carry out the tests. He considered, however, that doing so lowered his natural energy, and he thought that a sudden discontinuance of a daily practice must have some effect on the vital processes.

Livingstone College was established to give a training in hygiene and elementary medicine and surgery to missionaries. Mr. Cantlie spoke at the recent commemoration and declared it was doing a good work, for the course of instruction was good of its kind and well adapted to be useful to missionaries going abroad. He thought the great missionary societies ought to take the matter up, for it was wrong to send men out with no knowledge of medicine. I dare say he would agree with me that a full training would be very much better and that at every mission station there ought to be a qualified doctor. Some of the societies are establishing medical missions as a part of their regular work, but in other cases the want of medical aid by the missionaries themselves, as well as the people among whom they work, is felt to be a crying one.

Deputy Surgeon-General T. Ringer, who died in his eightieth year, entered the Indian Medical Service during the mutiny and was present at Lucknow and Delhi, for which he received a medal and clasp. He was a keen naturalist and archeologist. He retired in 1881.

On Tuesday night Dr. Duke, one of the resident staff at University College Hospital, met his death by falling down

the lift. He had gone to an upper floor to see a patient, and on returning seems to have thought the lift remained on that level and stepping in fell to the basement.

On Wednesday Lieutenant F. M. G. Tulloch, R.A.M.C., son of Surgeon-General Tulloch, died at the early age of twenty-seven. You will remember that he went to Uganda to investigate sleeping-sickness, and, as I reported to you, he contracted the disease. He took the double qualification of the London Colleges in 1901 and served as a civil surgeon in South Africa in 1902-3. On his return he was gazetted lieutenant in the Royal Army Medical Corps as from August, 1903. Towards the close of 1904 he was sent, under the Colonial Office, to Entibbe. When he was smitten with the disease he went to investigate he was invalided home and some hopes were entertained, but the progress was unusually rapid, and he succumbed on Wednesday, the 20th inst.

The death is announced of Dr. T. E. Hayward, M.B. London, F.R.C.S., Medical Officer of Health for Haydock, where he passed most of his professional life and where he achieved his high reputation as a statistician. He brought out life tables for two decades which were regarded as most valuable. His paper on a mode of constructing abbreviated tables for public health comparative statistics is quoted as the most authoritative, but it had been preceded by other contributions of scarcely less importance. In other work more closely related to the daily work of the practitioner he was also energetic, and his services were greatly esteemed in the community in which he resided.

OUR CANADIAN LETTER.

(From Our Special Correspondent.)

BRITISH MEDICAL ASSOCIATION—NEW HOSPITAL FOR TORONTO—INCREASE IN CANADIAN HOSPITALS—CRUSADE AGAINST PATENT MEDICINES—CANADIAN AND ONTARIO MEDICAL ASSOCIATIONS.

The local arrangements for the coming meeting of the British Medical Association at Toronto, August 21 to 25, are now about completed. It is quite evident that a large attendance will be recorded. More than 200 members, resident in the British Isles, have already reserved accommodations, and from the inquiries which have been made from every part of the American continent it is expected that the coming meeting will be the largest ever held in Canada. The local committees have been actively at work for several months, and strenuous efforts are being made to have all details carefully worked out. The association will be convened under thirteen sections, which will meet daily, from 9.30 to 1 o'clock. The afternoons and evenings will be devoted to general meetings, public addresses, and various entertainments. There will be three public addresses delivered, the orators being Sir James Barr, Dr. W. S. A. Griffith and Sir Victor Horsley. It is intended that clinics will be held each morning at 8.30, when interesting cases will be reviewed by some of the prominent physicians and surgeons in attendance. There is a pleasing indication of a large attendance of visitors from the American Medical Association. None will receive a more cordial welcome.

Toronto is likely to have a new hospital that will be thoroughly modern in every detail, and which will become an important addition to the clinical facilities in connection with the medical department of the Provincial University. The management is to be vested in a board of twenty-five trustees appointed by the Ontario Government, the University Council, the benefactors, and the City Council. This board has just been organized, and attention is now being given to secure suggestions in regard to the best hospital architecture in America and Europe. The site for the new hospital has been selected on University avenue convenient to the medical college.

The present Government of Ontario has been in power only a little over one year, but during that period has inaugurated several schemes for promoting not only the success of educational institutions but also has materially aided the hospitals and charities of the Province. There are now in Ontario over sixty public hospitals receiving Government aid in accordance with the number of patients treated. There are now nine institutions supported by the Government for the care and treatment of mental defectives. A special hospital for epileptics, to be conducted as a colony, located on a large farm, has just been opened near Woodstock in Oxford County. Nearly every county in Ontario has now a public hospital, and the scheme of supplementing local philanthropic efforts by generous aid from the provincial Government has resulted in the development of a hospital spirit that is most acceptable to the medical profession in Ontario. The other portions of Canada are also making commendable progress in the establishment of hospitals. The number of public hospitals in the other Canadian provinces now are: Quebec, 22; New Brunswick, 6; Nova Scotia, 3; Prince Edward Island, 2; Manitoba, 11; British Columbia, 12; Alberta, 5, and Saskatchewan, 2.

A vigorous campaign was inaugurated recently in Canada, having for its object the correction of some of the many evils of the patent medicine business. In both the Dominion and the Provincial Parliaments bills have been introduced compelling all engaged in the manufacture of proprietary medicines to publish the correct formula of each prescription in distinct and legible form on the label of each package, also compelling all manufacturers of patent medicines to have their products regularly analyzed by the Provincial Boards of Health. The public would in this way be protected and would be able to have definite and reliable information in regard to the ingredients of all proprietary medicines. Needless to say the opposition to these bills was most determined by the organized trade, backed up by local newspapers, who derive a large annual income for advertising and encouraging the sale of patent nostrums. In spite of this, however, the hope is well founded that very soon stringent restrictions will guard the sale of patent medicines in Canada.

On account of the meeting of the British Medical Association at Toronto in August the proceedings of both the Canadian and Ontario medical associations will be confined to executive work. Each of these organizations will convene at Toronto on the day previous to the meeting of the British Medical Association. At the meeting of the Canadian association a new constitution and by-laws will be presented as a report of the special committee on reorganization appointed at Halifax last year. The meeting of the Canadian Medical Association will be on the afternoon of August 20, and the meeting of the Ontario Medical Association on the evening of the same day.

Progress of Medical Science.

Boston Medical and Surgical Journal, July 5, 1906.

The Heart in the Puerperium.—H. Jackson reports two cases. The first one was apparently one of typhoid fever in the later stages of the puerperium, the heart action being rapid and feeble, suggesting an acute cardiac infection either muscular or valvular. The patient recovered. The second case was seen at the third month of a first pregnancy, the patient being a young woman of twenty-five years Two months later she complained of overaction of the heart. Two months later still she was seen in an attack of rapid, tumultuous heart action, it being impossible to determine the rate. Diagnosis was made of hypertrophy with tachycardia from overstrain. Rest in bed and proper remedies were ordered and in a short time she seemed as well as ever. She passed through her delivery in due time and without untoward incident. On the eighth day the tachycardia returned and was partially relieved. Soon a friction sound developed at the right base with an enlarged and pulsating liver. Toward the last a systolic murmur was heard over the latter, suggesting a marked tricuspid regurgitation evidently dependent on sudden dilatation of the heart. She died about four weeks after delivery. Sudden dyspnea at the close suggested pulmonary embolism. The case, therefore, was one without septic infection, but one of acute and fatal dilatation without demonstrable cause, except the effect of labor in a heart not previously absolutely sound, though no valvular disease had been detected at any of the numerous early examinations.

New York Medical Journal, July 30, 1906.

Thumb Sucking.—G. B. Webb employs the following preventive device. In a thin rubber ball of appropriate size an oval hole is cut to loosely fit the wrist, and the surface ventilated by very numerous punches with a stable harness punch. A cheesecloth bag of ample size is attached by stitches to the oval hole, and a tape run in and out of the cloth at this aperture, which can be gently tied at the wrist. A woolen mitten can be worn within this if required for cold weather. Several sizes have to be made at intervals of two months, to allow for growth. For a half hour night and morning these are removed and the child is taught gradually to pat-a-cake and play with its own hands. After four months the child will be completely broken of the habit, but still must wear the balls at night as a precautionary measure. The advantages of such a device are that the child can exercise and develop all its hand and

forearm muscles. It will also be of service with nail-biters.

Technique of Intramuscular Injections for Syphilis.—W. S. Gottheil describes this method in considerable detail. He reserves the use of soluble mercurials for those rare cases in which the luetic process threatens immediate damage to or destruction of important tissues or vital organs. This method, while efficacious, is painful, must be frequently repeated, and is often accompanied by salivation and gastroenteric troubles. The use of insoluble compounds establishes, so to speak, a medicinal depot in the tissues. The insoluble compound is slowly converted into a soluble one, and is gradually absorbed. The method is practically painless. After experimenting with various salts of mercury and various menstrua, he has adopted the salicylate suspended in liquid vaseline in the proportion of 10 per cent. by weight. An emulsion is formed, which flows easily through the needle. Ten drops equal one grain of the drug. The syringe employed should be used for no other purpose, and should be much heavier than the ordinary hypodermic. The needle should be about one and a half inches long. The needle ordinarily used for antitoxin injections answers every purpose. The fluid should be sterilized and kept in separate bottles, which can be placed in warm water when needed for use. The skin should be scrubbed with green soap and alcohol. The gluteal muscles should be used as the site of injection, which should be the center of the gluteal mass, about midway between the intergluteal fold and along the inner third of the region bounded by the fold and perpendicularly through the great trochanter on either side. The patient should stand erect during the injection. Just before the latter is made, the area selected (covered with sterile cotton after above-described cleansing) is bared and washed with ether. The needle is now quickly inserted for its entire length and the barrel contents discharged. The syringe is detached from the needle and the suspension-filled proximal end of the latter is carefully watched for a few seconds. If the point of the needle happens to be in a vein, the suspension will very slowly begin to well out of it; and if the vessel is a larger one, it will be followed by a drop of blood. The needle must then be withdrawn, and another puncture made, or the injection postponed. The precaution, however, must never be neglected. Oozing of blood after the injection is completed, showing that a vein has been traversed by the needle, does no harm at all. The implantation being found safe, the syringe is reapplied to the needle and the desired amount of suspension is injected. This should be done very slowly. The needle is then withdrawn as quickly as it was introduced, and the cutaneous orifice immeately closed with a pledget of cotton. A small piece of sterile zinc oxide plaster is then applied, to remain in place for a day, and the injection is completed.

Ocular Eczema in Children.—F. Krauss says that ocular eczema is a disease common in childhood, forming 21 per cent. of all eye diseases in children under sixteen years. It is most common at the age of two years, becoming less frequent as the age advances. It is endemic, but especially prevalent during the months of May, June, and April, in the order named. Treatment is very important in modifying its progress and tendency to relapse, and should comprise general treatment, with attention to diet and hygiene, as well as local treatment for the eye; the severer and stubborn cases quickly improve when rest in bed is required of the patient. The medicinal combinations which have given the author the greatest satisfaction are the following: For a tonic and alterative, syrups of iron iodide, hydriodic acid and hypophosphites; for a local wash, boric acid, cocaine, adrenalin, and distilled water; for eczema of the lids, boric acid in vaseline. When the cornea even at its periphery is attacked, it is advisable to put the ciliary body at rest at once by the use of a mydriatic, preferably atropine. The yellow mercuric oxide ointment, one grain to two drachms of petrolatum, introduced into the eye at night, causes rapid absorption of the phlyctenulæ. It should not be used in the earlier part of the disease, when the corneal lesion has reached the deeper layers, or when the eye is easily irritated. It does most good after the apex of the phlyctenulæ has ulcerated. Dark glasses should always be worn, on account of the photophobia. After the disease has passed the acute stage, insufflations of calomel or iodoform (of which the author prefers the former) into the ulcer act very beneficently. Ethyl morphine muriate solutions (4 to 15 per cent.) are of some benefit in aiding the disappearance of the resulting scar. The ulcer may require cauterization, but the resulting scar is apt to become, in these cases, quite opaque.

Fever in Childbed Due to Other Causes than Sepsis.—A. S. Wilner would divide the causes of this condition into psychical and physical. The former includes joy, fear, grief, fright, annoyance, too many visitors, etc. Of the latter, the most common is constipation. Other causes are overfeeding, improper diet, mammary gland disturbances, including nipple affections, absorption from wounds of the genital tract, retention of urine, and intercurrent diseases. Of these latter, malaria is the most common, but we may also have typhoid and scarlet fevers, diphtherias, tuberculosis, measles, smallpox, and pneumonia. The phenomena of labor may stir up old pelvic disorders. Of all these causes, each of which suggests its own treatment, the most common are constipation, overfeeding, and strong emotion. When these can be excluded, we must look, says the author, for some omission or commission with regard to asepsis. The article closes with some pertinent suggestions as to the conduct of the accoucheur.

Journal of the American Medical Association, July 7, 1906.

The Relation of Nerve Impulse to Cutaneous Inflammation.—E. L. McEwen discusses the problem of whether or not the process of inflammation can be produced by nerve impulse alone. He analyzes the different stages of the process and concludes that direct motor impulse can produce dilatation of the blood-vessels and secretion of fluid by the endothelium. It is possible that it may influence indirectly the slowing of the blood stream, the emigration of the leucocytes, and the readiness of the passage of the latter through the vessel walls. Motor impulse has no direct relation to the migration of leucocytes and proliferative tissue changes, and hence is not alone sufficient to produce inflammation. The factor necessary to supplement nerve action must embody the requirements of chemotaxis and the power of attracting leucocytes. This is found in external irritation. The four sources of irritation, chemical, mechanical, thermal, and actinic, by an analysis, may be narrowed down to one, namely, chemical. Chemical irritation has all the essentials for producing the full inflammation complex, initiating nerve action and supplying the other necessary factors. Products of protoplasmic degeneration or destruction, whether from trauma, perverted trophism, or disturbance of cellular nutrition, may be toxic to living cells and so furnish the needed chemical irritant for starting inflammation. This is probably the *modus operandi* in herpes. A purely reflex dermatitis is an impossibility, as every inflammatory skin lesion must have, from the nature of the pathological process, the factor of local toxic irritation in its etiology.

Lesions Predisposing to Cancer.—M. B. Hutchins enumerates the various skin lesions which may produce cancer, such as the irregular scaly, crusty, horny patches seen on certain skins, fissures, lupus, moles, *x*-ray ulcers, irritation from jagged tooth, also cases of so-called benign tumors and cysts. He urges the importance of attention to these conditions in time to prevent their malignant development, and gives brief reports of a number of illustrative cases.

The Reflexes of Dentition.—C. H. Dunn, while admitting the reflex element in certain of the symptoms credited to dentition, such as fever, aural disturbances, etc., maintains that the commonest symptoms seen in dentition are not reflex, but are due to pain. They may arise either from the tooth cutting the gum or from irritation of the root of the tooth. The majority of the symptoms attributed to a reflex irritation from the tooth, such as the skin exanthems, the ocular disturbances, and the respiratory disturbances, are probably mere coincidence. As to the digestive disorders considered as dental reflexes, he thinks a reflex causation is possible. Such nervous disturbances as muscular twitchings, tetany, and even convulsions, occurring during the eruption of the teeth and usually considered as reflex, he would hesitate positively to assign this cause. While we cannot deny that they may possibly be due to teething, he holds that there is little positive clinical evidence in favor of it.

Rocky Mountain Spotted Fever.—H. T. Ricketts, after a fairly exhaustive search of the blood in stained and unstained specimens in two cases, was unable to identify a parasite positively either within or without the erythrocytes. Similarly, cultures of the blood, made in bouillon and on agar plates of differing reactions, gave negative results, with one exception. In the one exception mentioned, a staphylococcus grew in a flask of bouillon which had been inoculated with from 3 to 5

c.c. of blood drawn from one patient. The results of experiments with rabbits and guinea pigs were somewhat surprising, since the failure to recognize the organism microscopically had suggested the probability that it was of exceedingly minute size and might be readily filterable. He would not assume that filtration is impossible, but states that it did not pass through the filter under the conditions of experiment. These experiments prove, then, that the condition produced in the guinea pig is an infection and not an intoxication, for otherwise the filtered serum undoubtedly would be as toxic as the unfiltered. In view of the infectiousness of the serum they also prove that the infecting agent is far from being an exclusive corpuscular parasite, and suggest very strongly that the organism is of such size that its ultimate and positive recognition with the microscope may reasonably be hoped for. Experiments with monkeys are also related. From these Ricketts concludes that the condition produced has been an actual infection rather than a transferred intoxication, because it can be passed through the second generation of animals, and because the filtered serum, which would certainly contain any soluble toxins which might be present, causes no disturbance when injected. No other cause of death in the animals experimented on could be found, and it was not possible to cultivate any microorganism from the heart's blood.

Harry N. Mayo describes the etiology, morbid anatomy, and symptoms of the disease. He states that the anatomic changes are those incident to purpura hemorrhagica. At first the spots resemble petechiæ, later they increase in size and extend over the entire body. The patient first complains of lassitude and shows an elevation of temperature to about 100° or 101°. As the spots appear the temperature rises, and there is headache, general malaise, loss of appetite, constipation, and coryza. The nervous symptoms are those usually accompanying febrile diseases. Mayo states that the disease is typical and could hardly be mistaken for anything else. The treatment, he says, must be in accord with the symptoms presented.

The Lancet, June 23, 1906.

Primary Pneumococcal Arthritis.—A general description of the affection is given by W. Pasteur and L. Courtauld, who describe one personal case, three from literature, and a fifth, which though not primary, contains certain points of interest. Their general conclusions are thus stated: (1) Primary pneumococcal arthritis is apparently of rare occurrence in adults. (2) In children it is less uncommon. (3) The path of infection is the blood stream, to which the organisms gain access through some slight and unnoticed area of injury. This is in all probability situated in the mouth, nasopharynx, or middle ear, and the relative frequency of this form of arthritis in infants and young children may be connected with their susceptibility to inflammatory conditions of these regions. (4) The infection is usually localized at first in one joint and may remain so; on the other hand, it may become generalized. (5) The death rate in the primary form compares very favorably with that of secondary pneumococcal arthritis. This may be accounted for by the usual restriction of infection in the former, whereas the latter generally implies a more or less pronounced septicemia. (6) It is probable that the records available do not convey an accurate idea of the frequency of this form of arthritis, as many slight cases, which recover without surgical interference, must escape bacteriological examination.

Congenital Hypertrophy of the Pylorus.—One personal case is reported by J. W. Rob. His patient was a healthy male child who at the end of the third week (as he did not seem to be gaining) was taken from the breast and artificially fed. Digestive troubles soon appeared. The bulk of the paper consists of details as to diet indication, etc., and cannot be reproduced here. No definite pyloric tumor could be felt, but the abnormally large size of the stomach and the forcible "pumping" vomiting led to the diagnosis given. No gastric peristalsis could be seen, although it could be felt. Later a pyloric swelling was detected, but disappeared. Under careful feeding the child was doing well at the seventh month.

British Medical Journal, June 23, 1906.

Copper Alginate.—A. and G. Gresswell enumerate some of the common uses of the familiar salts of copper, calling attention to the fact that in some animals this element is the essential metallic ingredient of the coloring matter of the red cells. They have employed copper alginate in pill form, 1-24 gr. to 1-6 gr., for simple and pernicious anemia. They have also used the salt in tuberculous ulceration of the bowel, but as other remedies were employed the value of the copper is decidedly problematical.

Neuritis in Phthisis.—A patient of J. Stark, a young man with tuberculosis, developed a typical wrist drop of the right hand. It was at first ascribed to pressure, but as it became permanent the author finally attributed it to the tuberculosis. This is a rare complication of the latter disease. Cases previously reported have presented lesions of the lower extremities, accompanied by excruciating pains. In the author's case there were no pain and the affected member was not sensitive to pressure.

Degeneration of the Myocardium in Hot Climates.—W. C. Brown calls attention to the fact brought out in the title of his paper. He considers the condition referred to as of great importance, for while the prognosis is, in case of prompt recognition and treatment, by no means bad, evidences of myocardial change are apt to be misinterpreted, and death not infrequently occurs after an apparently trivial illness. The disorder has no racial preference. Overindulgence in hard exercise is clearly causative. The middle-aged man who removes to the tropics and keeps up the athletic activities of his earlier years furnishes an especially fit subject. The patient has an indefinite malaise, but there is no faintness, dyspnea, cough, or precardial oppression. Cardiac rhythm is unimpaired, though the action is indicative of a flabby organ. Death may come in an anginoid seizure. It frequently occurs at night and after the administration of a hypnotic. Autopsy shows the heart somewhat enlarged, lax, and flaccid. Epicardial fat is markedly deficient. There is no endocarditis and no dilatation. Coronary arteries are dilated and soft. The myocardium is pale, soft, and friable. The intermuscular connective tissue is swollen and apparently increased in quantity, but round-celled infiltration and vascular congestion are absent. The tissue appears waterlogged, and in general it may be said that the condition is only a prominent feature of a general dyscrasia which affects all the tissues to a greater or less degree. The main principles of treatment are embraced in rest in bed, limited diet, general massage, avoidance of tobacco, and restriction of alcohol. Opium is the most valuable drug. Strychnine, digitalis, etc., are to be avoided.

Chorea Considered as Cerebral Rheumatism.—Dyce Duckworth gives his adherence to the infection theory of rheumatism, and admits the claims of Poynter, Paine, and others as to the isolation of the bacterial element therein. Chorea is also a manifestation of the infection. The old theory of nervous shock or fright in its causation must be abandoned, although we must acknowledge a neurotic factor in the pathogeny of the disease. The embolic theory, also, of causation is no longer tenable. That the young and the female sex afford the greater number of examples of chorea is probably due to the fact that in such subjects the rheumatic toxin is more apt to spread widely and to act with greater intensity than in adults. The adolescent brain is also more unstable than the adult one. Moreover, says the author, we have to bear in mind that the occurrence of chorea may be the sole manifestation of an attack of rheumatism in the absence of any concomitants, beyond possibly some degree of cardiac dilatation. It is thus a true cerebral rheumatism. This fact has not failed to inspire observers with doubt and incredulity as to the true rheumatic nature of the disorder. It is surely worthy of note that in first attacks of rheumatism and in first attacks of chorea there is not seldom to be observed a distinct degree of cardiac dilatation, sometimes independent of pyrexia, pericarditis, or appreciable endocarditis. This condition appears to be due to rheumatic toxemia, which induces a measure of myocarditis. In some of these cases the more ordinary rheumatic symptoms may supervene. The rheumatic toxin must possess a certain specific infecting quality, as we do not meet with chorea in cases of ordinary streptococcal infection or in strictly pyemic conditions. It is probable that there are variations in the quantity and degrees of virulence in the provoking toxin of rheumatism, which does not merely represent an alternated form of blood poisoning due to various pyogenic organisms.

Berliner klinische Wochenschrift, June 18, 1906.

The Causes of the Early Loss of the Teeth.—Warnekros describes at great length the mechanics of mastication, and points out that the loss of even a single tooth is of importance for the proper performance of the function. This is especially true for the

molars, and the absence of any one of these seriously disturbs the mechanics of mastication, and by causing undue and uneven wear to fall upon the other teeth brings about their premature loosening. In addition erosion and decay are favored, so that the loss of the first tooth should be the signal for prompt aid on the part of the dental surgeon to forestall subsequent damage. The loss of a single tooth is usually not regarded seriously, and the author holds that it is the duty of practitioners to counsel their patients to seek the dentist at once, and by providing themselves with a properly fitted prosthesis to prevent the tendency to further trouble.

The Therapeutic and Symptomatic Value of Lumbar Puncture in the Tuberculous Meningitis of Children.—Schlesinger says that four cases of tuberculous meningitis in which the bacilli were demonstrated in the spinal fluid obtained by lumbar puncture have been reported as having recovered. He considers that lumbar puncture offers the most promising therapeutic resource in these cases, and advises that it be repeated at intervals of from three to five days. It should be begun early and as much fluid as possible should be withdrawn, 50 c.c. or more. The danger of convulsions after withdrawal of cerebrospinal fluid seems to exist only in cases of brain tumor and need not be apprehended in dealing with children whose fontanel is still open. The only misadventure likely to be encountered is a so-called "dry tap," that is, although there is evidence of an excess of fluid in the ventricles, none can be obtained by lumbar puncture. This the author suggests may be due to a valvelike action, whereby the posterior cornua of the brain are forced so tightly against the margins of the foramen magnum, owing to the increased pressure, that no fluid can pass downward. The frequent repetition of the lumbar puncture is directly beneficial in preventing the convulsive seizures, and it is not unlikely that aside from its value in giving symptomatic relief it also influences favorably the actual course of the disease.

Münchener medizinische Wochenschrift, June 19, 1906.

Auscultation of the Spinal Column, Sacrum, and the Pelvis.—Ludloff states that he has found that much diagnostic information may be obtained by auscultation along the spinal column and over the pelvic bones. Many cases of backache, so-called occipital neuralgia, etc., may in this manner be discovered to be due to localized arthritis of the vertebral joints in question, owing to the very loud but sharply circumscribed crepitation to be heard with the stethoscope. Fractures of the vertebræ or about the pelvis may also be detected in the same manner.

Version in Placenta Previa.—Jolly is of the opinion that for the practitioner version is still the most advisable plan of procedure in dealing with placenta previa. He considers that if the cervix is still undilated it is much better to allow as much as possible of the liquor amnii to escape before attempting to seize the foot. When the cervix is dilated the version can, of course, be more easily performed if the uterus is distended with fluid, and under these conditions it is advisable to endeavor to prevent leakage as much as possible, but in placenta previa, owing to the fact that the seizure of the foot must be effected with one or two fingers, it is preferable to empty the uterus as completely as possible before attempting the version. This has another advantage, in that active pains and dilatation of the cervix are set up more rapidly if the liquor amnii has been allowed to escape, and as the period of birth is therefore shortened, the chances of securing a living child are greatly increased.

A Simple Method for Making Anaërobic Cultures.—Reuschel describes the following procedure. The test-tube to be used is provided at its open extremity with a piece of tightly fitting, thick-walled rubber tubing, which projects a short distance beyond the end of the tube. This is plugged with cotton and the tube containing the culture medium is sterilized as usual. The tube should contain more of the medium than is usually employed, so that it is about two-thirds full. The tube is heated so as to expel all air contained in the medium and is rapidly cooled. The inoculation is performed in the usual way, and by tipping the tube the upper layers of fluid are heated to the boiling point over a flame. In this way the upper portion of the tube is filled with water vapor and all air is expelled, while at the same time the organisms in the lower layers of the fluid are not injured. The rubber tube is closed with a clamp and the tube is placed in cold water, in order to cool it quickly. That all air has been expelled from such a tube is shown by the fact that if the lamp is removed from the rubber tube under water the entire test-tube will fill with the water. The author states that the most sensitive anaërobes can readily be grown by using this technique.

Deutsche medizinische Wochenschrift, June 21, 1906.

The Excretion of Sugar in the Urine in Pneumonia.—Rosenberger describes two cases of lobar pneumonia in which small quantities of a reducing substance were temporarily excreted. In the one instance, the patient being a boy of six years, it appeared that the condition was one of maltosuria, but in the other case, which was that of a woman of twenty-six years, the author was unable to arrive at a satisfactory conclusion in regard to the nature of the sugar. He suggests for the cause of this symptom that the pancreas in these cases may be the seat of a parenchymatous degeneration such as is commonly observed in other organs in the course of the acute infectious diseases. He considers that in the infectious diseases carbohydrates may be excreted in the urine, usually during only a short period of time and in small amounts, and independently of the diet, the body temperature, or the course of the disease. Neither the amount nor the specific gravity of the urine suggests their presence, and it is not unlikely that it may often be overlooked. The prognosis of glycosuria of this sort does not appear to be bad, and the symptom usually disappears of itself without being affected by the further course of the infectious disease. A tendency to the excretion of glycuronic acid or sugar after carbohydrate feeding may persist. Both of the author's patients recovered completely.

A Simplified Method for the Quantitative Determination of the Uric Acid in Urine.—Kowarski describes the following procedure, which he says has the advantages of simplicity and rapidity without any sacrifice of accuracy. Ten c.c. of urine is put in a small centrifuge tube and two or three drops of ammonia and 3 g. of powdered ammonium chloride are added. The tube is closed with a rubber stopper and shaken until the ammonium chloride has dissolved. The tube is allowed to stand for two hours, during which time the ammonium urate formed separates. The fluid is then centrifuged during one or two minutes and the supernatent fluid is poured off. Five drops of concentrated hydrochloric acid are added and the tube is heated over a small flame; a crystalline deposit of uric acid promptly forms and the tube is allowed to stand for an hour. The sediment is washed with water and alcohol by means of the centrifuge until the alcohol has a neutral reaction. The sediment is then dissolved in 2 c.c. of hot water, a drop of phenolphthalein is added, and the hot fluid is titrated with 1-50 normal piperidin solution until a permanent pink color is obtained. The number of milligrams of uric acid present in the 10 c.c. of urine is obtained by multiplying the number of c.c. of piperidin solution used by the factor 3.36. The author has found that the results obtained compare favorably with those of the Salkowski or Hopkins method, and the procedure has the further advantage of not requiring more apparatus than is usually to be found in the physician's office.

French and Italian Journals.

The Use of Alcohol in Gastric Pathology.—Paul Carnot has been investigating a new method of determining the secretions of the stomach. It consists in provoking gastric secretion by the ingestion of a small quantity of alcohol and of analyzing this secretion. While normal stomachs react very similarly in the production of an acid secretion rich in pepsin, diseased stomachs act in a very different manner. Some produce a hyperacid and hyperpeptic secretion; others a hypoacid and hypopeptic secretion. In a large number of cases (atrophic cirrhosis and cancer of the stomach) the gastric glands do not react at all to alcohol. In other cases (certain forms of gastritis) the secretion is not acid, but is rich in pepsin. Finally, in other cases the reaction is muciparous. It would seem from these experiments that alcohol may give very helpful indications in the different pathological processes.—*La Presse Médicale*, May 10, 1906

Treatment of Whooping-Cough by Chloroform Narcosis.—Henri de Rothschild has recently observed the remarkable effect of chloroform anesthesia on a child suffering from whooping-cough. The chloroform was administered to the little patient for the purpose of reducing the hip. The child had been suffering from whooping-cough for eight days. At the time of writing this child had been under observation for more than fifteen days, but had not had one coughing spell during that time, although before the anesthesia she had suf-

fered from about thirty-nine attacks a day. Vomiting, cyanosis of the face, and insomnia have also ceased. This observation led the writer to suppose that chloroform anesthesia might have a distinctly beneficial influence on whooping-cough, especially at the beginning. He has tried this method on other children. In these cases the results have been most encouraging. The duration of the anesthesia is five minutes. Complete anesthesia is not attempted. The stage of muscular relaxation before reaching the point of abolition of the corneal reflex gives the best results. In no case has the writer practised a second anesthesia.—*Le Bulletin Médical*, May 23, 1906.

Metastasis of Cancer of the Soft Parts of the Thigh.—Vian reports this case. The patient was a woman sixty-one years old. On the internal surface of the thigh was an oblong tumor, solid, and movable from side to side. The inguinal ganglia were not palpable. Operation was performed and the growth was found to be a fibromyoma, having its origin in the muscular layer of the femoral vein. Within a year the patient had a recurrence. Operation was again performed, but on account of adhesions to the large vessels the tumor could not be entirely removed. Some days later amputation of the thigh was practised. This time examination showed the growth to be a fasciculated sarcoma, or rather a fibrosarcoma. A few months later the patient returned to the hospital with a dorsal tumor. At operation this growth was found to be under the muscles. The seventh, eighth, and ninth spinous apophyses had been destroyed by the growth. Microscopical examination showed this new tumor to be a fasciculated sarcoma. The localization of the metastasis in the vertebral column is not common to sarcomata. The transformation of fibromyoma into sarcoma is exceptional.—*Le Progrès Médical*, May 19, 1906.

Researches on the Hibernal Whitening of Hair and Feathers.—Elie Metchnikoff has been making a special study of old age. The phenomenon of the blanching of the hair has been investigated. In a work published five years ago he said that the loss of pigment in the hair was due to the action of certain cells, which he called chromophages. This theory did not agree with the one commonly accepted, that of the penetration of the air. Metchnikoff believes from his studies that human hair, hair of the lower animals, and feathers contain living elements sensitive to outside influences, and capable of moving and of seizing grains of pigment. In other words, these chromophages show the highest functions of the cell. Their existence explains how the influence of strong emotions in man may blanch the hair in a night. Under the influence of violent excitement these little elements may become particularly active. These studies also serve to explain the whitening of the fur of certain animals in the winter.—*Gazette des Hôpitaux Civils et Militaires*, May 22, 1906.

Clinical Experiments on the Complements.—D. Pacchioni and A. Mori give us a résumé of the most important conclusions obtained from the determination of the quantity of complements existing in the blood of twenty-nine infants sick or convalescent from different diseases. The complements are contained in the blood in a fixed and determined quantity, which varies with morbid conditions, lessening in some diseases and increasing in acute infective diseases in the beginning of the attack. In tuberculosis, typhoid, and purulent arthritis, the complement was the same as in normal infants, In nephritis, one case of tuberculosis, and scarlatina the quantity was from two to four times less than normal. In varicella and pneumonia, the complements were increased in the beginning of the attack and decreased in the successive days.—*Lo Sperimentale*, Vol. LX, Part II.

Echinococcus Cysts of the Liver and Kidney.—Gaspare Alagna describes a case diagnosed as cyst of the liver in which, when the abdomen was opened, it was found that there were cysts of both liver and kidney. The kidney was reduced to a cyst the size of an orange, with a connective tissue capsule, the renal tissue having been almost entirely destroyed so that the cyst appeared to be connected with the intestine to which it had become adherent. As such it was removed, and only the microscopical examination of the specimen revealed the existence of a small amount of degenerated renal tissue. Such cysts are exceedingly rare, there being records of but ten to be found in medical literature. It is usually impossible to diagnosticate them during life, as they produce no renal symptoms at all. This case occurred in a child of twelve years. All the other recorded cases have occurred in adults.—*La Riforma Medica*, April, 1906.

Books Received.

While the Medical Record is prepared to receive all trade publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.

[illegible] B.A. (Cantab), M.B., C.M., F.F.P.S. (Glasg.). 12mo, 547 pages, muslin. William Wood & Co., New York. Price, $2.75, net.

[illegible] TIONS AND WOUND TREATMENT. By C. YELVERTON PEARSON, M.D., M.Ch., F.R.C.S. 8vo, 392 pages, illustrated, muslin. William Wood & Co., New York. Price, $3.50, net.

Book Reviews.

A Manual and Atlas of Dissection. By Simon Menno Yutzy, M.D., Instructor in Osteology and Demonstrator of Anatomy in the University of Michigan. With 314 illustrations. With an introduction by J. Playfair McMurrich, A.M., Ph.D., Professor of Anatomy, University of Michigan, Ann Arbor. Philadelphia: P. Blakiston's Son & Co., 1906.

This volume is designed to help the student in his work in the dissecting room, and it is well adapted for this purpose. The student will find here a list of the structures which he should identify and study, and also some concise directions as to how to proceed with his dissection; but for a description of the structures named, and for all details of anatomy he must refer to his text-book. The book is profusely illustrated, and almost all of the cuts are taken from Holden's or Morris' Anatomy. The volume is well printed, strongly bound, and it will lie open at any desired page.

The Modern Materia Medica. The Source, Chemical and Physical Properties, Therapeutic Action, Dosage, Antidotes, and Incompatibles of all Additions to the Newer Materia Medica that are likely to be called for in Prescriptions. New York: The Druggists' Circular, 1906.

With the ever-increasing number of therapeutic agents, most of them fortunately of purely ephemeral interest, that are offered by the manufacturing chemists, it is impossible for the ordinary practitioner to keep their often confusingly similar names straight in his mind, even if it were worth while to do so. There are times, however, when it is desirable to have some means of securing at least a superficial idea of the nature of some particular agent, and then the present compilation may be found very useful. The descriptions of the various drugs appear to be fairly impartial and the list seems as nearly complete as is possible in dealing with such a mushroom growth. For another edition we would suggest the addition of an index of the chemical names of the substances, for many old acquaintances become wholly unrecognizable when attired in the polysyllabic disguise that these ultraethical days seem to require.

A Textbook on the Practice of Gynecology. For Practitioners and Students. By W. Easterly Ashton, M.D., LL.D., Fellow of the American Gynecological Society; Professor of Gynecology in the Medico-Chirurgical College of Philadelphia. Second Edition, Revised. With 1,046 original line drawings. Philadelphia and London: W. B. Saunders Company, 1906.

As it is less than a year since the first edition of this work appeared we naturally expect to find but few alterations in the text; a few typographical errors have been corrected, and there is some change in several of the illustrations. The most noticeable features of this work are that it is intended for the general practitioner rather than for the specialist; that it gives in considerable detail all that should be done in any given case, and tells not only what to do, but also how to do it; the general arrangement of the work is also different from that of any other book on the subject, and it will particularly appeal to those for whom the book is intended. The illustrations are numerous and helpful. Of course every method described by the author will not be indorsed as the best possible procedure by every gynecologist; but the general practitioner will find this a safe guide, and a more than ordinarily useful one. That there is ample room for a book of this sort, and that it supplies a want, is evidenced by the short time that has elapsed since the issue of the first edition. One adverse criticism that we would make is on the spaced type so freely used, presumably for emphasis; it is very trying to the eyes.

Chemistry of the Proteids. By Gustav Mann, M.D. (Edin.), B.Sc. (Oxon.), University Demonstrator of Physiology, Oxford. Based on Professor Otto Cohnheim's "Chemie der Eiweisskörper." London: Macmillan & Co., Limited; New York: The Macmillan Company, 1906.

The author of this work is not one of those who see in the phenomena of cellular metabolism manifestations of so-called "vital" processes whose true inwardness forms a mystery that the human mind must not hope to solve. The volume is rather an expression of scientific optimism, and the reader who follows the steps by which so many of the problems of organic chemistry have been unraveled can but share the author's hopefulness in regard to future work. The present book is founded largely on Cohnheim's treatise on the same subject, of which it was the author's original aim to present simply a translation; but, as he explains, the work grew under his hands to such an extent that finally he decided, with Cohnheim's consent, to assume the whole responsibility for it. For those who are acquainted with the "Physiological Histology" of the same author no commendatory phrases are necessary in regard to his present contribution, but for those who are not and who would inform themselves as to the present standpoint of knowledge in this intricate field, it may be stated that it is without doubt the most satisfactory exposition of the subject to-day extant in English. The synthesis of albumins forms one of the most interesting chapters of the book and is given in detail as far as developed up to September, 1905.

A Compend of Obstetrics, especially adapted to the use of Medical Students and Physicians. By Henry G. Landis, A.M., M.D., Late Professor of Obstetrics and Diseases of Women in Starling Medical College. Revised and edited by William H. Wells, M.D., Demonstrator of Clinical Obstetrics in the Jefferson Medical College, Philadelphia; Gynecologist to the Mount Sinai Hospital, Philadelphia; Late Adjunct Professor of Obstetrics and Diseases of Infancy in the Philadelphia Polyclinic; Fellow of the College of Physicians, and of the Gynecological section of the same; Member of the Pediatric Society of Philadelphia, etc., etc. Eighth edition, illustrated. Philadelphia: P. Blakiston's Son & Co., 1906.

As this compend has reached its eighth edition, it may be presumed to have justified its existence. The present issue contains three or four new illustrations taken from Edgar's book on obstetrics, an occasional new paragraph in the body of the work, and an appendix of some obstetrical constants.

The Examination of the Function of the Intestines, by means of the Test-Diet. By Prof. Dr. A. Schmidt. Translated by Charles D. Aaron, M.D. Philadelphia: F. A. Davis Company, 1906.

Aaron's translation of this important and practical booklet of Prof. Schmidt is an excellent one. In order to be able to judge of abnormal processes within the intestines through an examination of the feces a standard diet must be given. This, according to Schmidt, should consist of 1.5 liters milk, 100 gm. zwieback, 2 eggs, 50 gm. butter, 125 gm. beef, 190 gm. potatoes, and gruel of 80 gm. oatmeal. It contains about 102 gm. albumin, 111 gm. fat, 191 gm. carbohydrates, or a total of 2,234 calories. The test is generally given for three days, sometimes longer, at any rate until a stool is obtained which comes with certainty from this diet. With a normal evacuation this occurs with the second defecation after the beginning of the diet. The patient as a rule does not need to take a special powder in order to mark off the normal excrement from the excrement of the former diet, for the normal excrement can generally be recognized at once by its uniform consistency and its lighter color. For a macroscopical examination the excrement is first stirred up thoroughly with a wooden spatula, and a small amount of about the size of a walnut is transferred to a glass mortar (of about 12 centimeters in diameter). In this it is ground up as fine as possible with the addition of at first a few cubic centimeters and gradually more distilled water (until it is of fluid consistency). The grinding up must be done carefully, so that no coloring excrement particles remain. The ground-up specimen of excrement is then spread over a flatback plate or a large glass vessel in as thin a layer as possible and account is taken of all the elements that are still recognizable in it with the naked eye.

Under pathological conditions then appear: Mucus, in larger and smaller, even very small flakes; remains of connective tissue and tendons from the chopped meat eaten; remains of muscular tissue; potato remains; large crystals of ammonia, magnesium phosphate.

A Text-Book of Human Physiology, Including a Section on Physiological Apparatus. By Albert P. Brubacker, A.M., M.D., Professor of Physiology and Hygiene in the Jefferson Medical College; Professor of Physiology in the Pennsylvania College of Medical Surgery; Lecturer on Physiology and Hygiene in the Drexel Institute of Art, Science, and Industry. Second edition, revised and enlarged. Philadelphia: P. Blakiston's Son & Co., 1905.

The first edition of this work was well received by teachers and students of physiology, although not superior to some of the already existing books on the subject. It is well, however, to have more than one text-book on any subject, especially one of this nature, in order that facts regarding some of the more obscure points may be stated in different ways and so be more readily understood. The present edition is an improvement on the first in that certain obscure sections have been rewritten and the inevitable inaccuracies of a first edition have been corrected. The new views of digestion brought to light by Pavlov, Cannon, and others are noted, and new matter on the nervous mechanism of the heart and on vision has been introduced. The work as it is now improved compares most favorably with other physiological text-books, and can be recommended to students as a safe and satisfactory guide.

Society Reports.

ILLINOIS STATE MEDICAL SOCIETY.

Fifty-sixth Annual Meeting, Held at Springfield, May 15, 16, and 17, 1906.

DR. H. C. MITCHELL, OF CARBONDALE, PRESIDENT.

THE society met in the First Methodist Church. Its scientific work was divided into two sections, medical and surgical.

MEDICAL SECTION.

Duties and Obligations Relating to Tuberculosis.—Dr. C. W. LILLIE of East St. Louis dealt with what might be termed the ethical aspects of this subject. The paper dealt with the duties of parents and guardians; of teachers in our common schools; of employers of labor of all kinds; of city and county officials and boards of health and overseers of the poor; of legislators, governors, and others whose duty it was to promote the passage of laws for the preservation of public health; of charitable persons in each community; of philanthropic and wealthy citizens; of managers of steam and street railways; of hotel proprietors; of the individual in his personal habits; of all doctors, and especially members of State, county, and city medical societies. The doctor's duty more particularly was to make sure of his diagnosis. Lastly, the author pointed out the duty of the doctor to instruct all others in regard to tuberculosis.

Etiology and Diagnosis of Tuberculous Spondylitis in Infancy and Childhood.—Dr. J. H. HESS of Chicago read a paper on this subject, in which he reported two interesting cases, and emphasized the great importance of early *x*-ray examinations in these cases. This was clearly illustrated in the first case, in which the degree of destruction, though only moderate, could be localized beyond a doubt. He also pointed out the common danger of misinterpreting the reflected pains as local diseases in the parts affected, as illustrated by conclusions in both of the cases reported.

Congenital Syphilis in the Infant.—Dr. I A. ABT of Chicago discussed the treatment of this condition in infants. He pointed out the indications for treatment, and remedies employed, choice of drugs, plans of treatment, etc.

Hysteria in Children.—Dr. D'ORSAY HECHT of Chicago said that this subject merited the attention of the general practitioner and specialist in pediatrics and neurology. Inquiry into hysteria in children had not been a searching one. The general belief was that hysteria was a malady of adult life. He spoke of the physical and mental factors conducive to the development of hysteria in children. He considered the symptoms and cited several illustrative cases. The diagnosis was discussed with special reference to the exclusion of organic disease, the recognition of organic disease complicated by hysteria, and the detection of simulation. The prognosis and treatment were likewise discussed briefly.

Intestinal Disorders of Children.—Dr. JOHN C. COOK of Chicago discussed the etiology, the bacterial findings, the pathological lesion, and the treatment, both dietetic and medical, of the intestinal disorders of children, accompanied with diarrhea.

Infant Feeding.—Dr. A. C. COTTON of Chicago followed with a paper, in which he gave some practical points on infant feeding.

Manifestations of Rheumatic Infection in Children.—Dr. C. MARTIN WOOD of Decatur pointed out the difference between adults and children in their reaction to rheumatic infection, and said that there was more extensive and lasting damage in the latter. He spoke of tonsillitis, endocarditis, arthritis, chorea, and erythemas as rheumatic manifestations. He likewise discussed their differential diagnosis. He emphasized the importance of recognizing both mild and obscure cases. He said there was a marked tendency on the part of some children to frequent outbreaks in one family or another. This was due to a lessened resistance, either hereditary or acquired. The protection of the heart and the prevention of fresh attacks should be the main object of treatment. The former was secured by rest and counteracting of poisons, while the latter was obtained by hygienic management, especially of clothing, exercise, and bathing.

The Attitude of the Physician Toward the Nostrum Evil.—Dr. CHARLES SPENCER WILLIAMSON of Chicago said that a very small part of the knowledge and energy which every physician is constantly giving to his work would, if applied to the eradication of the nostrum evil, do away with it in a very short time. Already there were signs of improvement. In another city where the nostrum evil had reached, a year or so ago, even a worse stage than in Chicago, he found from the last two hundred prescriptions taken consecutively but twenty-one calling for proprietaries. This number was, of course, still large, greatly in excess of the justifiable proportion, and yet it showed that the diminution to one-half or one-third of this figure should be readily obtained. All that was necessary was to arouse the profession thoroughly to the exact situation, and it would do as it always had done before—act promptly and efficiently, and wipe out this blot upon its fair name.

Disease in the Aged.—Dr. W. H. CURTIS of Wilmington in a paper on this subject drew the following conclusions: "(1) While the first requisite for longevity may perhaps be deemed to be an inborn, perhaps inherited quality of tissue structure wherein one part shall be just as strong as another, like the materials of the famous One Hoss Shay, it is still manifestly possible and sometimes practicable to detect the onset of those pathological processes frequently originating in middle life, and whose development is synonymous with that symptom-complex known as old age. And, further, when a diagnosis is thus made, it is possible and frequently practicable to institute therapeutic measures that will insure the prolongation of the individual life. (2) The study of the processes of disease in the aged, together with their appropriate therapeutics, offers a rich field for individual research, and one that deserves more thorough cultivation. In this connection our present knowledge of the subject needs thorough revision, amplification and systematization at competent hands, and to be made more accessible. (3) It is requisite to the successful study of disease in the aged, and certainly almost essential to the one who undertakes their management that he be possessed of a peculiar mentality, combining not only a liberal education, but great resourcefulness in tact, patience, and sympathy."

The Macroscopical Agglutination of the Typhoid Bacilli as a Diagnostic Test for the General Practitioner.—Dr. A. M. STOBER of Chicago read a paper in which he discussed this question.

Lordosis.—Dr. M. S. MARCY of Peoria reported an interesting case of lumbar lordosis.

Treatment of Obesity.—Dr. ALFRED C. CROFTAN of Chicago presented some newer ideas on the treatment of this condition. He discussed the science and art of reduction cures, the calorimetric method, the three degrees of obesity and their management, the restriction of liquids, the element of exercise, the treatment of complications, thyroid therapy and results.

Significance of Hydrochloric Acid Variation in the Stomach Contents.—Dr. E. J. BROWN of Decatur spoke of the relative importance of HCl determination to other chemical findings, and to the physical examination of the stomach. Errors in diagnosis were made by placing too much reliance upon HCl tests. He spoke of the relations of HCl excess to so-called bilious attacks, muscular rheumatism, gout, eczema, etc. He emphasized, too, the value of HCl tests in hyperchlorhydria, achylia gastrica, gastritis, cancer, ulcer, and neurasthenic gastrica. He dis-

cussed some of the new methods in diagnosis of diseases of the stomach.

Serous Inflammations.—In a symposium on this subject papers were read by Dr. A. A. Goldsmith of Chicago, Dr. L. C. Taylor of Springfield, Dr. C. A. Elliott of Chicago, Dr. N. S. Davis of Chicago, Dr. Wm. A. Evans of Chicago, Dr. C. L. Mix of Chicago, and Dr. E. E. Kerr of Chicago.

Interstate Reciprocity.—Dr. J. A. Egan of Springfield read a paper in which he discussed facts and fallacies concerning interstate reciprocity in medical licenses.

The Opium Habit and Its Treatment.—Dr. George F. Butler of Chicago briefly outlined the general line of treatment he usually adopted. There was, however, no systematic routine specific treatment for this disease. The patient and not the disease, here as in all cases, was first to be considered. He first ascertained the maximum dose and the total daily amount of the drug the patient was taking. Then he began the gradual or more rapid withdrawal of the morphine, the method employed being governed entirely by the character of the case. Under no circumstances must the patient know the amount he was given at any stage of the treatment. If he was taking it hypodermically, he endeavored to abandon the use of the needle as soon as possible, without detriment to the patient, substituting deodorized tincture of opium or codeine in some vehicle, preferably non-alcoholic, which would completely disguise the taste of the opium. The patient was invariably encouraged when he could to abandon the use of the hypodermic syringe. The opium in the mixture for internal use could be diminished as required. Free elimination by the bowels, skin, and kidneys must be maintained. Many other adjuncts to treatment were discussed in detail. He believed morphinism could be cured in the great majority of cases if the physician could have the confidence and entire control of the patient, and had him in an institution where all the facilities for proper treatment were at hand, and provided he could keep the patient under observation a sufficient length of time and would treat the patient mentally and physically, and not merely the disease, according to some routine method.

Serum Therapy.—Dr. E. R. Larned of Chicago gave an epitome of the progress of serum therapy during the last year. He classified sera as to their being efficient or inefficient. He spoke of efforts to produce new sera; also of the attempts made to improve sera which had been inefficient for the purposes intended. He spoke of the investigations that had been carried on with reference to making antigonorrheal and antisyphilitic serum. Attention was directed to modifications of the Widal test for the diagnosis of typhoid fever, and of Wassermann's serum in the treatment of diphtheria.

Defects of Vision and Hearing in the Public Schools.—Papers were read on this subject by Drs. J. Whitfield Smith of Bloomington, Frank P. Norbury of Jacksonville, A. L. Adams of Jacksonville, and James A. Egan of Springfield.

Many other papers were read before the Section on Medicine.

GENERAL SESSION.

At the evening session of the first day, an address was delivered by Governor Charles S. Deneen. The Governor selected for his subject, "Crime as a Social Disease." He confined his remarks mostly to crime in Cook County, where for eight years he was State's Attorney, and was brought face to face with some of the worst criminals and criminal cases in the world, in a district which was noted as the worst criminal district in the world. While crime had existed in the world almost from the beginning, it was only a comparatively late thing that it was being unearthed by modern methods, and it was only within the past twenty-five years that criminal procedure had been directed at the source of crime. The criminal court of Cook County was the greatest in the world. This court had a record of four thousand prosecutions annually by the State's Attorney of Cook County. He closed by saying that crime offered one of the widest fields for medical opportunity in the country.

President's Address.—This was delivered by Dr. H. C. Fairbrother of Carbondale. His subject was "Popular Diffusion of Medical Knowledge." He brought forth the fact that the educated were the best class of people with whom the doctors had to deal; that there was less disease as the people advanced in the educational scale, and that the educated were the most reasonable to deal with. He also stated that the Society should advocate the passage of a law compelling people who wished to marry to undergo a physical and mental examination before entering upon matrimony, and thus allay much of the suffering caused by immature marriage and consequent evil and sickness. Such a measure, he said, would cheat the divorce courts and the jails of their patrons.

The Address on Surgery was delivered by Dr. D. W. Graham of Chicago, who selected for his subject, "Some Hindrances to Surgical Progress."

SURGICAL SECTION.

Perirectal Abscess.—Dr. Charles J. Drueck of Chicago emphasized the frequently overlooked details in the treatment of perirectal abscess, and took up the pathology, symptoms, and diagnosis. Under treatment he considered the necessity of immediate evacuation. He referred to the facts and fallacies of the different methods of obtaining drainage, and made a few remarks relative to the method employed by him. He spoke of the danger of autointoxication and pelvic congestion during the postoperative treatment, and how to prevent it.

The Brain a Good Field for Surgery.—Dr Charles D. Center of Quincy made an effort to show by numerous well-authenticated cases of traumatism that many portions of the brain need not be considered vital parts; that less reluctance should be shown by surgeons in invading the brain under antiseptic precautions, the argument being based on the insensitiveness of the brain to injury. The reason for much unsatisfactory brain surgery in the past was that operative measures had been used too much as a last resort instead of a first resort, and operation had been done in the presence of inflammation, sepsis, or both. He reported a case of gunshot wound of the brain where the ball traversed the brain once in antero-posterior diameter, and partially traversed again in ricochet. Skiagraphs of the head of the patient at the present time were exhibited, and some interesting phenomena were noticed during the progress of the case.

Renal Diagnosis, with Reference to Nephrotomy, Nephrectomy, Nephrorrhaphy, and Plastic Pelviureteral Surgery.—Dr. Frederick Leusman of Chicago, in a paper on this subject, submitted the following conclusions: (1) Functional tests were helpful in causing us to study the kidney more accurately before operation. Their findings were not without value, but experience showed we could do as well without as with their assistance. When employing them in order to save life, we must at times operate, despite their findings. (2) The cystoscope and urethral catheter had come to stay, and familiarity with their use was becoming more general every day. They were indispensable diagnostic aids. (3) Time would show the practical value or worthlessness of other diagnostic methods. (4) A chemical, microscopical and bacteriological examination of the urine obtained from the ureteral catheter frequently meant much to the patient. (5) The *x*-ray was desirable, if obtainable. (6) An early incision into the kidney in the presence of symptoms pointing to renal surgery was the safest thing for the patient. (7) Do not explore during suppurating conditions. (8) Most kidney operations demanded probing to test ureteral

patency. (8) Experience demanded early nephrolithotomy as soon as the existence of stone was established; early nephrectomy in renal tuberculosis, and early nephrotomy or nephrectomy in acute renal abscess. (10) Nephrotomy was safer than nephrectomy in calculus, especially multiple; also in nephritis and cystic kidney. (11) In doing renal surgery we must not neglect to take care of the associated abdominal pathology—stomach ulcer, duodenal ulcer, cholelithiasis and cholecystitis, appendicitis, intestinal stricture or tumor, intestinal tuberculosis, uterine and pelvic adnexa disease.

Treatment of Compound Fractures.—Dr. Edward H. Ochsner of Chicago pointed out in what cases the limb can be saved, and when primary amputation is justifiable. He spoke of the method of disinfection, including prevention of tetanus. He pointed out the indications of plastic work in the repair of bones, tendons, nerves, etc., and discussed the method of drainage and wound closure. Also secondary shock and immobilization.

The Use of Extension Frames in the Treatment of Fractures of the Thigh and Leg by Ambulatory Casts.—Dr. Frederick Mueller of Chicago said the ambulatory plaster cast was the most convenient and natural treatment for all fractures of the thigh or leg. Its application was dangerous in some cases, on account of the possibility of disarranging a fracture once set. The author described a new apparatus which, beside showing all the advantages of the Lorenz apparatus, was especially built for general use in the treatment of fractures. The setting of all kinds of fractures could be accomplished by this apparatus with the greatest convenience for the surgeon as well as for the patient.

The Operative Treatment in Fractures Presenting Obstacles to Reduction.—Dr. William Fuller of Chicago drew the following conclusions: (1) That the unsatisfactory results hitherto obtained in practically all cases when treated conservatively would not meet the continued approval of surgeons familiar with modern surgical technique. (2) That the indications for radical treatment were positive and certain, and that the safety of the procedure was unquestioned. (3) That the operation offered in this class of cases the only reliable means of arriving at a correct diagnosis, the only basis upon which rational and scientific treatment may be enunciated.

Dr. W. R. Cubbins of Chicago discussed the Roentgen ray in fractures, and Dr. A. E. Halstead of Chicago spoke of pathological fractures resulting from metastatic carcinoma.

Problems in Appendicitis.—Dr. H. N. Rafferty of Robinson said that the appendicitis question, although hackneyed, was unsettled in many respects, as shown by bedside contact with individual cases. There was nothing new to offer in the way of diagnosis or treatment. All extremes had been reached in formulating methods of treatment, yet mortality prevailed. He pointed out the difference between radical conservatism and conservative radicalism. Difficulty in the conduct of cases was often due to inability to judge the extent of the lesions from either subjective or objective symptoms. The author, in closing, pointed out how much safer for both patient and practitioner was the doctrine of conservative radicalism over that of radical conservatism.

Angioma and Its Surgical Treatment.—Dr. Carl Beck of Chicago gave a brief historical review of this condition and its treatment, and dealt with the present method of surgery in angiomatous growths. He referred to the Payr and Wyeth method; to excision; electro-surgical method, and described his own method of subcutaneous excision and suture with the gradual growth of normal neighboring skin.

Shortening of the Round Ligaments at the Internal Ring for Persistent Retroversion of the Uterus.—Dr. Franklin H. Martin of Chicago gave a description of the technique of shortening the round ligaments through the internal ring after opening the abdomen by a ventral incision. It was accomplished by making a stab wound through the aponeurosis of the external oblique at the point where it passed over the internal ring. Through this opening was passed a pair of sharp artery forceps, penetrating the peritoneum at the point beneath the internal ring, grasping the round ligament within an inch and a half of its insertion into the uterus, and drawing the same through upon the aponeurosis and securing it there by means of a non-absorbable suture. He considered the operation unique in its simplicity; there was perfect security of the round ligaments. He employed the strong ends of the round ligaments and shortened the ligaments in the line of their normal axis.

Complications and Emergencies Met With in the Surgical Treatment of Ovarian Cystoma.—Dr. George L. Eyster of Rock Island enumerated and described the various complications of ovarian cystoma: Twisting of the pedicle; hemorrhage into the cyst; infection and suppuration; adhesions; displacement due to enlargement of other pelvic or abdominal organs. He made a plea for the split flap method of relieving such sessile adhesions to the abdominal viscera as might endanger their integrity by the ordinary method of enucleation. He reported two interesting cases illustrating some of these complications and emergencies.

The Need of Publicity in Venereal Prophylaxis.—Dr. Denslow Lewis of Chicago said it was the duty of the profession in every township to disseminate a knowledge of the truth regarding the prevalence of venereal diseases. He said the necessity of active endeavor everywhere should excite every humanitarian to do his utmost by a consistent prophylaxis to diminish the ravages of these loathsome diseases.

Symposium on Surgery of the Prostate Gland.—Dr. Carl E. Black of Jacksonville spoke on "How Can We Secure the Cooperation of the General Practitioner in the Surgical Treatment of the Enlarged Prostate?" He gave the history of surgery of the prostate, with special reference to surgical failures and their influence on the profession. He said it was not surprising that it was difficult to have the present operations accepted. What proof was there of the correctness of the present surgical procedures? He spoke of the influence of medical organizations in disseminating information, and their use for post-graduate instruction. He pointed out the apparent conflict between medical and surgical advice, and referred to the weakening influence of the division of the profession into societies and sections of specialists. He discussed the value of papers on surgical topics by general practitioners.

Dr. F. Kreissl of Chicago followed with a paper in which he gave the present status of the Bottini treatment. He reviewed the recent literature on the subject, discussed the operation and its underlying principles, together with the technique, immediate and final results. He spoke of the failures and fatalities, and their causes.

Dr. M. R. Barker of Chicago discussed the disarrangement and destruction of vesical structures in hypertrophied prostate and consequent functional disturbances. Postoperative urinary troubles were due to these conditions and not to the operation. What should be the attitude of the physician toward these patients when he first saw them, and what might he expect from his patients from surgical procedures?

Dr. John B. Murphy of Chicago pointed out the indications for, the limitations, and clinical results of, prostatectomy, saying that the indications were now well accepted and clean-cut. The early operation was the one that preceded catheter life, severe vesical infection, not to speak of ascending pyelitis. The technical procedure as to route was always elective in the individual case. The results had been very gratifying as to urinary continence, as to dispensing with the catheter, the cure of suppurative cystitis, absence of fistulæ, prevention of epididymitis, and

life-saving. There was no operation that taxed the surgeon's judgment as to the personal resistance equation so much as the operation of prostatectomy.

Dr. Alexander Hugh Ferguson of Chicago followed with a paper in which he discussed perineal prostatectomy as the operation of choice.

Vasectomy With or Without Subsequent Anastomosis, with Special Reference to the Treatment of Certain Inflammatory and Neuropathic Disturbances of the Male Sexual Apparatus.—Dr. G. Frank Lydston of Chicago said that the operation of vasectomy was a legitimate means of relief for certain conditions. Cord operations in suitable cases had a profound influence on the innervation and circulatory supply of the prostate and seminal vesicles, and incidentally a marked effect upon nutrition must result. Vasectomy was not indicated in any case in which there was a reasonable probability of relief being afforded by less radical means. The operation, when properly performed, was practically free from danger. Vasectomy had a certain range of application in sexual neurasthenics, spermatophobiacs and in genuine spermatorrhea. The operation was of the greatest value in intractable chronic prostatitis and seminal vesiculitis. Its beneficial effects were due not only to the change which it induced in the circulation and innervation of the prostate, but also to the rest which it secured to the seminal vesicles. Vasectomy had a certain range of application in suspected or known tuberculosis or malignant disease of the testis. In inoperable malignant disease of the prostate with severe hemorrhages, vasectomy had, in the author's experience, been beneficial. He described the technique of the operation of anastomosis of the vasa deferentia. In a certain as yet undetermined proportion of cases it was possible to so anastomose the divided vasa deferentia as to reestablish their continuity. Of four cases operated on in this manner, one had shown a restoration of function of the vas on one or both sides by the presence of spermatozoids. Of the other three, one was apparently a failure. There had been no opportunity to determine the condition of the remaining two.

Sarcoma in Childhood.—Dr. W. K. Newcomb of Champaign reported a case of sarcoma in a child, three and a half years old, and exhibited the specimen.

Treatment of Blenorrhea of the Lacrymal Sac, with Special Reference to Sac Extirpation.—Dr. W. O. Nance of Chicago said that chronic dacryocystitis is an exceedingly annoying process, and a source of danger to the integrity of the eye. The course of the disease was almost invariably obstinate and frequently resulted in months and even years of treatment by probing, syringing, and correction of nasal abnormalities. The removal or destruction of the diseased mucous membrane of the lacrymal nasal duct was positively obligatory as a preliminary to operation upon the globe of the eye. He pointed out the other indications for extirpation of the sac, and suggested some practical points concerning the technique of operation. He spoke of the essentials of success in operating, and described the changes in the lacrymal gland following the extirpation of the sac.

The Operative Treatment of Chronic Discharges from the Ear.—Dr. A. E. Prince of Springfield said a very large percentage of cases of middle ear discharge was due to chronic suppurative mastoiditis. He pointed out the complications which were liable to result when the disease was not controlled. Attention was directed to the results of the efforts of nature to bring about a spontaneous cure. It was the duty of the surgeon to assist nature. He spoke of the results of imperfect operations in which the surgeon had failed to remove all of the cells, which actually increased the danger of fatality. He summarized the points in the radical operation which were designed to bring about a permanent cure in the least possible time, and cited illustrative cases.

Symposium on Carcinoma.—Dr. George N. Kreider of Springfield spoke of the popular agitation for the early operative treatment in carcinoma. Cancer was a frequent and increasing disease. He referred to the remarkable superstitions about the disease, and said that the affection was not so fatal as was generally supposed. There was great need of teaching physicians and the public the early symptoms. Reference was made to the great number of uneducated persons who were using the strongest, most painful means of treating the disease. Washes and salves were entirely useless. All abnormal growths should be extirpated early. Early extirpation in cancer was absolutely necessary. Inoperable cases should be treated with the *x*-ray, and the patient be given hopes of recovery.

The Operative Treatment of Superficial Carcinomata.—Dr. Daniel N. Eisendrath of Chicago said that by superficial carcinomata are understood those of the lip, tongue, ear, extremities, and external genitalia. The reason for recurrence in many of these cases was that no attention, or but little, had been paid to the removal of the secondary deposits in the surgical anatomy of the lymphatic supply of the above regions. He made a plea for a thorough removal of the secondary foci simultaneously with the extirpation of the primary growth, saying that the two operations can be done at one sitting. The extirpation of lymph nodes should precede that of the primary tumor on account of the lesser danger of infection of the operative field. He described the technique as used by him in his surgical work.

The Logic of Abdominal Pain.—Dr. J. L. Wiggins of East St. Louis said that one of the fallacies that was general among the laity and altogether too prevalent among physicians was that the summoning of the surgeon presumed an operation. Another equally vicious was that operations were expedient only as a last resource. Considering the frequency with which these errors obtained, the surprise was not that surgery fell short of perfection, but that it was not altogether discredited. When we considered the safety and simplicity of an operation when a disease was in its incipiency and confined within the lumen of a dispensable organ, and then contemplated the rapid change incident to the escape of infectious material and consequent local or general peritonitis, we felt that the surgeon might be absolved from the charge of excessive zeal in his endeavor to impress upon the general profession the vital importance of an early and exact diagnosis, supplemented by an immediate operation whenever an operation was indicated.

Many other excellent papers were read.

Officers.—The following officers were elected for the ensuing year: *President,* Dr. J. F. Percy of Galesburg; *First Vice-President,* Dr. L. H. A. Nickerson of Quincy; *Second Vice-President,* Dr. James H. Stowell of Chicago; *Secretary,* Dr. E. W. Weis of Ottawa, reelected; *Treasurer,* Dr. E. J. Brown of Decatur, reelected.

Resolutions.—The following resolutions were adopted by the Society:

Resolved, That the Committee on Medical Legislation be instructed and the members of the Society urged to work for the passage of the bill by the next General Assembly of Illinois which shall provide that all bottles or packages containing drugs shall bear a statement on the label of the quantity or proportions of alcohol, narcotics, or other poisons which may be contained therein.

Resolved, That the Illinois State Medical Society directs its Committee on Medical Legislation and urges its members to do what they can to secure the passage of the Pure Food Bill now before the House of Representatives, except the amendment introduced into the bill by the House Committee, providing for the appointment of a Commission of Experts. It requests that this amendment, which would probably decrease the efficiency of the measure, be eliminated.

Resolved further, That the Committee on Medical Legislation and the members of the Society be requested to

oppose any amendment to this bill that would essentially change the provision of the bill as it came from the House Committee, requiring the labeling of medical packages containing alcohol, narcotics, and other poisons.

Resolved, That the Illinois State Medical Society directs its Committee on Medical Legislation, and urges its members to do what they can to secure the passage of the bill to increase the efficiency of the medical department of the army, which is now before the House of Representatives.

Resolved, That the Illinois State Medical Society fully endorses the campaign of education and of practical work against the nostrum evil in its various phases, and urges its officers and members to cooperate in every way to further this cause.

Hereafter Papers to Be Read Before the General Body.—It was also resolved that, as this was largely a society of general practitioners who are of necessity interested in all branches of medicine and surgery, the Committee on Scientific Work should be instructed for the next year's program to provide one day for the medical section, at which papers on purely medical subjects shall be presented; one day for the surgical section, at which papers on purely surgical subjects shall be presented; and one day for a joint meeting, at which papers on borderland subjects and subjects of mutual interest to all shall be presented.

Rockford was selected as the place for holding the next annual meeting, the third Tuesday in May, 1907.

NEW YORK ACADEMY OF MEDICINE.

Regular Meeting, Held May 3, 1906.

DR. CHARLES L. DANA IN THE CHAIR.

Memorial Address on the Late Dr. George Ryerson Fowler.—Prof. A. T. BRISTOW of Brooklyn, Ex-President New York State Medical Society, read this memorial.

Presentation of a Patient Shot Through the Abdomen, Liver, and Spinal Cord. Laparotomy, Laminectomy, Recovery.—Dr. IRVING S. HAYNES reported this case of V. C., Italian girl, twelve years of age, who was accidentally shot by a 32-caliber bullet, the entrance of the wound being at the left of the median line, three and one-half inches below the ensiform appendix. The bullet could be seen at the right of the middle line of the back, at the eleventh dorsal spine. Examination revealed a small pulse, extreme pallor, dyspnea, cold skin, restlessness, and thirst. The lower extremities were very hyperesthetic from the middle of the thighs downward. The legs were moved slowly and with difficulty. Ankle motion very slight. Dr. Moorehead operated, closing the orifices of entrance and exit in the liver with No. 2 chromic gut. The abdomen was made clean and the abdominal wound sutured. The bullet was removed. The lower extremities were still hyperesthetic and there was incontinence of urine and feces. The accident occurred on October 28, and on November 3 the patient showed anesthesia corresponding to the terminal distribution of the musculocutaneous, small sciatic, and external saphenous nerves, and motor and sensory paralyses of the anterior tibial, posterior tibial and its branches, and of the anus and vesical sphincter. There was also anesthesia of the skin of the buttocks, perineum, and inner side of the thighs. In view of the extension of the paralysis an exploratory operation on the cord was deemed advisable and a laminectomy was performed on November 3. The bullet had passed between the laminæ of the eleventh and twelfth dorsal vertebræ, close to the base of the spinous process of the upper one. Both laminæ were slightly notched by the bullet. The posterior arches of the eleventh and twelfth dorsal and first lumbar vertebræ were removed. No blood clot external to the dura was found. The dura had a small, round hole in its center at about the middle of the field. The cord showed directly in its center a small mushy area where it had been traversed by the bullet, though it was not severed. The dura was sutured with a fine catgut continuous suture. Heavier interrupted catgut was used for the deep muscles. A few silkworm gut strands were left in place for drainage. On November 8 the drain was removed and the wound healed *per primam.* The course of the case was very tedious, there being incontinence of urine and feces and constant pain in the legs below the knees. On November 13 there was slight general wasting of both legs, with absence of both knee-jerks and plantar reflexes. The galvanic current was used every other day and right-angled splints applied to the feet. By December 17 the patient had regained control of the bladder and rectum. By January 4 the patient had been out of bed for a week and pulse and temperature were normal. By January 23 all sensation above the level of the crest of the ilium was normal. Anteriorly, internally, and externally sensations were normal as far as the knees. On the outer side of the right knee pain and temperature sense were disturbed. There was complete anesthesia of the greater portion of the surface of the right foot. There was marked disturbance of sensation for pain and for temperature from the upper part of the buttocks to just above the knee. Flexion of the knee was very weak and of the right ankle it was absent. The patient walked with typical ataxia gait. On February 9 the general motor power was very much improved, but the right anterior tibial group was still paralyzed. The reflexes and sensations remained practically the same.

Dr. WM. M. LESZYNSKY, who had recently examined the patient, said that no knee-jerks were present, and that the weakness of the flexures of the thigh was more marked on the right side. There was also a slight foot drop on this same side. The condition of bladder and rectum was normal. The Faradic irritability in the perineal nerves was preserved. There was no marked atrophy. The Faradic irritability was quantitatively diminished in the muscles. The girl had made a decided improvement. The reflexes had always been absent. There was anesthesia for pain, touch, and temperature of the right leg.

Gunshot Wounds of the Spinal Cord: A Plea for Early Myelorrhaphy.—Dr. IRVING S. HAYNES said that this paper was written to advocate early interference in the worst cases of spinal injury, and while only gunshot wounds were dealt with, the argument, proof, and conclusions were equally applicable to the severer forms of fracture, dislocation, and traumatism. He described the pathology of this class of cases as limited to the findings within the spinal cord. The symptoms which followed cord injury were produced by an interference with the conductivity or interruption of the continuity of the nerve fibers, or a disturbance or destruction of the nerve cells reflected in various motor and sensory symptoms and alteration in the reflexes in parts situated below the seat of the lesion. There was no symptom or group of symptoms that would prove that the cord was severed within a reasonable time. As to treatment, he thought that all patients who survived the initial shock of the injury to the cord should be operated upon. The damaged region should be laid bare in order that the extent of the injury might be ascertained and the proper treatment instituted. The total mortality in non-operated cases was 69¼ per cent. and in operated cases 42½ per cent. It was generally conceded that laminectomy was imperative in the following conditions: (1) To remove the bullet, or spicules of bone or particles of clothing; (2) to remove blood clots; (3) to arrest hemorrhage; (4) to allow for oozing in traumatic edema of the cord; (5) to prevent pressure and sepsis by free drainage; (6) in advancing paralysis; (7) to suture a cord was a proposition not universally accepted, but it was upon this subject that he wished to devote his time.

The idea back of the advice for early interference was not to attack a severed cord, primarily, but to operate in the hope of finding and alleviating the less serious conditions, before compression of the cord had produced secondary de-

generation. As this set in at an early date operation must be correspondingly early. His reasons for radical operation were: First, in regard to the anatomical possibility of suturing severed cords where there had been loss of substance, the feasibility of suture of the cord had been demonstrated in the living when there had been separation of the ends to the extent of three-fourths of an inch. In work on the cadaver he had demonstrated that coaptation was possible after resection of three-fourths of an inch in the dorsal and one-half in the cervical regions. Such resection was followed by retraction of the ends of the cord to a much wider interval than was occupied by the segment removed. An essential step in the operation which rendered coaptation possible after the loss of three-fourths of an inch was full extension of the spine and head. He thought that cadaver work did not express the full possibilities of spinal-cord resection in the living. In the upper dorsal and cervical regions freer mobility and easier coaptations of the severed ends could be obtained by tearing off with a blunt hook the attachment to the dura of two pairs of the serrations of the dentate ligament above and below the site of the section. Second: As to the possibility of several cords uniting, it had been demonstrated that in animals hemisections of the cord always united. This was true of complete sections, though in the latter case there was a retraction of the ends and the interval was filled in with a blood clot, followed by a cicatrix. In human beings Chipault stated that the results following severance of the spinal cords by a stab wound were ordinarily complete recovery. In gunshot, fracture, and dislocation lesions attended by destruction of tissue the ends of the cord had been united in five cases with evidences of union of the severed ends in all. Third: As to whether such microscopical union was attended with true microscopical union or regeneration, experimental evidence of several observers after transection of the spinal cord found nerve fibers traversing the cicatrix, which were considered traceable to an efferent root adjacent, being able to trace them to a spinal ganglion. From an exhaustive paper by Strobe we learned that the fibers of the posterior roots, at the level of the lesions, grew out from the side of the spinal ganglions and pushed their way a distance between the fibroblasts of the cicatrix. These new fibers looked like the regenerating fibers of divided peripheral nerves. These fibers were not full size, and at the end of forty-five days had not produced anything like genuine regeneration of the cord. A study of these experiments proved very conclusively that in no case was the severed cord sutured, and consequently a blood clot formed which retracted to a greater or less extent, so that it was no wonder that continuity of the cord was not established in forty-five days. Several cases were cited where the cord had been sutured with apparent success. One case in the Montreal General Hospital was operated on eleven months after the injury had been received. The interval between the ends of the cord had increased to one and one-half inches and a segment three inches long of the spinal cord of a large dog was placed alongside of the severed ends of the patient's cord. This patient died a month later from an abscess of the right kidney. Autopsy showed that there was typical ascending degeneration of the columns of Goll and Burdach above the site of the lesion. Sections below the lesion showed definite degeneration in the direct and crossed pyramidal tracts. The dura and tissues at the site of the grafting showed a mass of minute myelin sheaths of nerve fibers which lay closely adherent to the dura and united with the segments of the cord above and below, demonstrating that regeneration of the axones of the spinal neurones had taken place to a limited extent. Two other cases by Estes and Fowler confirmed the preceding results. Every case of complete transverse lesion of the cord not operated upon had died in less than a year, while of the five operated upon one died in ten days and the others were living and improving, having lived from two and one half to eight years after the injury. As to the operation upon the spinal cord, the dura should be opened in every case for the full extent of the wound. Two or four traction sutures should be placed in the cut edge; they were better than clamps or tenacula and were not in the way. The bullet, spicules of bone, foreign bodies and blood clots should be removed, the latter preferably with a stream of saline solution. By drawing on the traction sutures and lifting up, the cord was brought into better view. If it was completely severed the bruised and lacerated ends should be carefully trimmed and then brought into coaptation. Fine chromic catgut sutures should be introduced well away from the severed ends, so that in tying they would not cut through the cord. One suture was passed anteroposteriorly through the center of the cord and the other two from side to side, one near the ventral the other near the dorsal surface of the cord. The trunk should be kept fully extended until the operation had been completed and a plaster jacket applied. The sutures should be tied in the cord, the mushroomed ends smoothed out, and the dura closely adjusted by three interrupted sutures. Drainage should be from the dura outward with strands of silkworm gut or strips of rubber tissue for twenty-four hours. Operation should be performed at the earliest possible moment after recovery from the initial shock of the injury or after dealing with the serious complications of abdominal or thoracic lesions. The after-treatment was important. Immediately after operation the indication was rest for the spine, the body being maintained in the fully extended position. The jacket could be removed in from two to three weeks and active electrical stimulation with massage and passive motion should be undertaken. Retention apparatus should be employed to prevent deformities in the limbs. The bladder should be carefully catheterized and irrigated and everything pertaining to the preservation of strength, nutrition, and comfort should be utilized.

Dr. George E. Brewer said that the case reported was a surgical triumph. His own experience with spinal surgery, however, for traumatism had led him to change his views. Following the advice of Boston surgeons and neurologists, who advised operating upon all cases of spinal injury, it was his practice to make an exploratory laminectomy in every case of fracture or dislocation of the spine, in the hope that he might, by the relief of pressure, removing the blood clots, etc., bring about a restoration of function. In five or six years not a single case received any benefit where there were evidences of a transverse lesion of the cord. Therefore he abandoned this plan. Dr. Brewer said that five or six years ago there was a patient at the City Hospital with a transverse lesion of the cord following a fracture in the mid-dorsal region. When the dura was seen it was found to be dark colored, but the cord was found to be apparently normal except that it was surrounded by blood clots. The removal of these clots was not followed by benefit. Death later resulted, and at autopsy the cord showed no grave lesions except the blood clots surrounding it. This led him to believe that many of these cases were due to the presence of blood clots. As yet there was no proof that complete transverse crushing injuries are benefited by operation. It was his habit now to discourage operations in all such cases; but where there were evidences of partial lesions he encouraged operation. Dr. Haynes' case was one of incomplete lesion of the cord in the upper segment, and the brilliant results obtained were due to this fact. In cases of gunshot wounds nothing can be definitely learned except by an exploratory operation, which he believed should always be done in such cases.

Dr. Samuel Lloyd considered the question of regeneration of the spinal cord and called attention to the fact that Dr. Dana was one of the first to take up this subject. Dr. Lloyd said he had had two cases in which he tried to get the cord together following complete transverse injuries. In one case he succeeded in getting the cord together and improvement followed. In the other case, one of gunshot wound in which the injury was in the fifth lumbar seg-

ment, a similar attempt was made, but little improvement resulted. Another consideration to be taken into account was not only how much improvement was due to the regeneration of the cord, but also how much improvement was due to the recovery of the cord from the injury or destruction. In all these cases he said there was apoplexy of the cord and improvement followed the absorption of these hemorrhagic areas. This should be taken into account before one decided that the full recovery of function was due to the regeneration of the cord itself. In fractures of the arch operation should be invariably undertaken, and early operation should be emphasized, giving a sufficient length of time first for the patient to recover from the shock of the injury, unless symptoms are present calling for immediate operation, such as increasing paralysis.

Dr. G. M. Hammond said that the case presented was a very interesting one, but he was not sure that the cord had been wounded at all—at least he did not believe the bullet had wounded the cord. The electrical reactions were normal; there was no muscular atrophy, there was no injury to the motor tract, no contractures, rigidity, clonus, exaggerated reflexes; in short, there were no symptoms which made it appear that there was any lesion of the motor columns of the cord. There was a loss of the muscular sense and sensory symptoms which showed the possibility of some lesion of the posterior roots or columns of the cord; but in the case reported it would have been impossible for the bullet to injure the posterior portion without some injury to its anterior portion. The fact, too, that the patient was improving was to him an argument that they were not dealing with a gunshot wound of the cord. Regeneration of a cord so torn by a bullet was impossible.

Dr. J. J. Moorhead said that at the time of the patient's entrance into the hospital there was little in her appearance that made them suspicious of spinal involvement because of the absence of gross sensory or motor paralysis. Then, too, the bullet was subcutaneously palpable well outside the median spinal line and there were no signs of bone splintering. The immediate diagnosis of abdominal hemorrhage from penetrated viscera was readily apparent, and when it was seen that only one edge of the liver was involved, surprise was expressed that it was possible for a bullet to traverse the cavity in the manner related without doing greater damage. The following morning the bullet was extracted, and the patient's complaints of sensitiveness in the lower extremities seemed so disproportionate to her good condition that she was thought be somewhat hysterical. With this definite destruction of spinal marrow, there was lack of absolute corroboration until the cord was exposed; in fact, the operation was performed under the impression that a hematomyelia had occurred. Surprise was again expressed when it was apparent that the bullet had traversed an intevertebral disk and there was little or no pressure, hemorrhage, or clot, and that the symptoms were due to a definite loss of tissue bored out by the traversing bullet as by an augur. With regard to the theories of restoration of function, he said that it appeared that such could take place on the basis of (1) regeneration of axones; (2) anostomotic action compensating for destroyed fibers; (3) vicarious action on the part of uninvolved sections; (4) union of individual fibers, as occurred in peripheral nerves, and (5) organization by blood clot. At the present state of our knowledge regarding spinal function the weight of authority was not with any one of the above, but he thought that further investigation would probably show that a combination of factors was responsible.

Prof. Trendelenburg of Leipzig said that a year and a half ago he and his assistants had made a great many experiments, cutting and suturing the spinal cords of twenty-five cats and dogs. The cats died but the dogs lived long enough to show results. Some dogs died at the end of a few weeks, some at the end of a few months, from kidney involvement. One of the dogs lived one year and two months. None of the dogs ever had regeneration of the cord or its fibers, so far as could be determined. The post mortem showed a mass of cicatricial tissue in the gap caused by the retracted cord. He thought that if the animals could be kept quiet other results would have been obtained; but in their moving about the ends of the cord were torn asunder.

Dr. Wm. M. Leszynsky said that the bullet went through the cord and that certain symptoms presented by the patient without any doubt pointed to the spinal lesion.

Dr. George Woolsey said that his experience in the treatment of fractures of the spine had been like Dr. Brewer's, and he had never had any good results from operation when there had occurred a complete severance of the cord. Where there was a fracture of the posterior portion of the spine, operation should be undertaken. The lower down the fracture, the better the prognosis. Operation should be more often undertaken the lower down in the column the fracture was; one could not be sure whether complete paralysis would occur until time had elapsed, and he believed the cases should be given the benefit of the doubt in the way of operative treatment. Personally he had but little faith in operating when there was a complete severance of the cord. He said he was not enthusiastic regarding suturing the spinal cord. The anatomical regeneration of the cord had not been proven, although he believed that a few of the nerve fibers might become regenerated. He called attention to a boy who was brought to Bellevue Hospital a year ago last February with a complete crushing injury of the cord, as evidenced by complete motor and sensory paralyses below a certain line. The symptoms persisted for weeks and he did not suppose the patient would ever be able to leave his bed. Later on he was surprised to see him up and around the ward. This boy recovered under expectant treatment and the results were as good as those obtained in Dr. Hart's case, in which the cord was sutured. It was astonishing how many and what good recoveries were reported after such a severe accident.

Dr. Charles L. Dana called attention to the brilliant success attending nerve suturing and grafts, and said that all knew that in cases of crushing injuries of the spinal cord no restoration of function could occur except by the renewal of spinal cord tissue. In certain locations he did not see why one could not take a motor nerve above the lesion, bring it down, and suture it to another motor nerve below. It seemed to him feasible.

Dr. Haynes, in answer to Dr. Hammond's statement that he did not believe the bullet had injured the cord directly, said that the bullet did go through the spinal cord and the case presented was a good argument that regeneration had taken place. One never knew just what happened to the cord after an injury, fracture, or dislocation unless one opened up the spinal canal. He thought that the cases reported that recovered from apparent transverse complete lesion without operation were open to serious questioning. There were a few cases of complete division of the cord where the patient lived for from five to eighteen years, but at autopsy it was found that the lesion had not been a complete one. This seemed to bear out the contention that all cases of complete transverse division of the spinal cord had died, and died within one year. The longest authentic case he knew of lived 265 days. The completeness of the recoveries had given rise to much debate, but whether the cord regenerated *in toto* or in part there seemed to be no doubt that there was some sort of union. Muscles that hitherto had not been capable of moving were moved; regions not sensitive before operation became sensitive after. He believed that the argument was a strong one that, in spite of the experiments performed upon animals, better results had been obtained in the case of human beings, and one must believe that there had been fibrous unions or that regeneration had taken place.

State Medical Licensing Boards.

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE.	NAME AND ADDRESS OF SECRETARY.	PLACE AND DATE OF NEXT EXAMINATION.	
Alabama*	W. H. Sanders, Montgomery	Montgomery	August 1–6
Arizona*	Ancil Martin, Phoenix	Phoenix	October 1
Arkansas*	J. P. Runyan, Little Rock	Little Rock	October 9
California	Chas. L. Tisdale, 530 California Street, San Francisco	San Francisco	August 21

* No reciprocity recognized by these States.

† Applicants should in every case write to the secretary for latest details regarding the examination in any particular State.

North Carolina.—At the examination held in May, 1906, there were 131 applicants; of this number 86 passed and 45 failed.

Texas.—From May 1, 1905, to April 10, 1906, there were 185 applicants for the State board examination; of these 112 passed and 73 failed. Under the reciprocity clause three licenses were granted, the States thus recognized being Virginia and New Jersey.

South Carolina and Georgia.—Reciprocal relations which formerly existed between these two States have been broken on the ground that the Georgia standard is not up to that of South Carolina. The Georgia board has been notified that South Carolina will not again reciprocate with their State until they raise their requirements

Illinois reciprocates under certain conditions with Indiana, Iowa, Kansas, Maine, Maryland, Michigan, Minnesota, Nebraska, New Jersey, North Dakota, Ohio, South Carolina, Vermont, Wisconsin, and Wyoming.

Indiana reciprocates under certain conditions with Georgia, Illinois, Iowa, Kansas, Kentucky, Maine, Michigan, Missouri, Nebraska, Ohio, Virginia, and Wisconsin.

North Dakota reciprocates under certain conditions with Illinois, Maine, Michigan, Vermont, and Wyoming.

New Jersey reciprocates under certain conditions with Illinois, Maine, Michigan, New York, Ohio, and Vermont. Her licenses are endorsed by Delaware, Illinois, Iowa, Kansas, Colorado, Maine, Michigan, Minnesota, Missouri, New York, Ohio, South Carolina, Texas, Vermont, Virginia, and Wisconsin.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the City, for the week ending July 7, 1906.

	Cases	Deaths
Tuberculosis Pulmonalis	343	161
Diphtheria	220	27
Measles	370	19
Scarlet Fever	103	6
Smallpox	—	—
Varicella	28	—
Typhoid Fever	45	10
Whooping Cough	36	4
Cerebrospinal Meningitis	27	16
Malarial Fever		
Totals	1,172	243

The Normal Microbism of the Appendix.—A. Gilbert and A. Lippmann have conducted a series of experiments in order to determine the normal bacteria of the appendix. These experiments deal solely with the rabbit and the dog, on account of the extreme difficulty of obtaining the human appendix free from all infection. These investigators conclude from their results that in the normal state the appendix in its entirety is the seat of a microbic flora of great variety and of extreme abundance. They also call attention to the preponderance of the colon bacillus.—*Le Bulletin Médical.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon General, Public Health and Marine Hospital Service for the week ending July 7, 1906.

MULTIPLE MOTOR NEURITIS, INCLUDING LANDRY'S PARALYSIS AND LEAD PALSY;*

WITH REPORTS OF CASES.

By WILLIAM G. SPILLER, M.D.,

PHILADELPHIA.

PROFESSOR OF NEUROPATHOLOGY, AND ASSOCIATE PROFESSOR OF NEUROLOGY IN THE UNIVERSITY OF PENNSYLVANIA.

AND WARFIELD T. LONGCOPE, M.D.,

PHILADELPHIA.

DIRECTOR OF THE AYER CLINICAL LABORATORY OF THE PENNSYLVANIA HOSPITAL.

CASES of rapidly developing paralysis of all four limbs are not common. Undoubtedly many classed as Landry's paralysis are caused by neuritis, but to assume that all have this etiology, as some writers have done, is unjustifiable. The literature of Landry's paralysis has become so extensive that it is inadvisable to review it. The subject has recently been discussed by Hans Lohrisch,[1] and the report of his case, among others, shows that Landry's paralysis may be spinal in origin. Lohrisch found disease of the gray matter in all parts of the spinal cord and medulla oblongata, as shown by hemorrhages, degeneration of medullary sheaths in the gray matter, degeneration of the nerve cells and of the anterior roots. He describes it as a diffuse acute poliomyelitis. The peripheral nerves were not examined. The patient had tabes also. There seems to have been no round-cell infiltration in the spinal cord.

The case of acute, rapidly-developing paralysis like that of Landry's paralysis, reported by one of us (Dr. Spiller[2]) in association with Dr. Sherman, showed much more intense alteration of the spinal cord than that reported by Lohrisch.

A recent case of acute ascending paralysis, with necropsy, reported by Edwin Bramwell,[3] is explained by him as the result of a toxic process acting upon the lower neurones. Degenerative changes were found in the facial and external popliteal nerves and tibialis anticus muscle. Bilateral facial palsy was an unusual complication of the acute palsy, and the paralysis first appeared in the face. The histological examination of the tissues for bacteria was negative.

Landry's paralysis is not always fatal. Some years ago one of us (Dr. Spiller[4]) reported a case of this type in which complete recovery occurred, and similar cases are recorded in the literature.

Buzzard[5] says that enlargement of the spleen and extensive pleurisy in the form of old or recent adhesions are found frequently in Landry's paralysis, and these lesions seem to indicate an infection.

A case of acute anterior poliomyelitis causing rapidly ascending paralysis has been reported recently by F. A. Hoch[6] with a review of the literature of this disease.

A case by Mills and Spiller[7] in which the peripheral motor neurones alone were affected was reported, with a careful review of the literature of the subject, in 1898. A still more recent paper on Landry's paralysis is by Peter Bassoe.[8]

Instead of discussing the subject of Landry's paralysis separately, we have preferred to include it under the heading of multiple motor neuritis. As already said, we do not ignore the spinal form of this symptom-complex.

The selective action of poisons for certain portions of the central or peripheral nervous system is one of the most striking facts of medicine. In uremia, whatever the intoxication may be, we see at times focal cerebral symptoms, and we are in the habit of explaining these on the theory of a locus minoris resistentiæ. Unquestionably similar symptoms are caused by arteriosclerosis, and we have been familiar with these at least more than ten years and have frequently referred to them, but to explain all uremic focal symptoms as the result of arteriosclerosis is unwarrantable.

In tabes, a metasyphilitic disease, we have the action of some poison on the posterior roots. Why the posterior roots should be implicated instead of the anterior we cannot say.

In tetanus we have the implication of the motor system, and in some cases paralysis of the facial nerve, a motor nerve. Alcohol and nicotine select the papillomacular bundle; diphtheria especially the nerve fibers to the ciliary muscle, and lead the distribution of the posterior interosseous nerve. Cramer[9] has referred to the fact that Arneth, on account of the appearance of the neutrophile leucocytes in the agonal period of Landry's paralysis and tetanus, made the inference that in both affections the central nervous system forms the point of attack of the infection. As Arneth puts it: "We shall hardly err if we ascribe to the poison of Landry's paralysis an exclusive affinity for the central nervous system."

Peculiar to Landry's paralysis is its irresistible course. Von Leyden in 1893 said that multiple neuritis requires less time for its development, and may become manifest very rapidly, and shows little tendency to the orderly extension, the gradual and steady progression, of Landry's palsy. Still, multiple neuritis of the ordinary type is at times confined to the lower limbs, in which Landry's paralysis usually develops, as in a recent case, with necropsy, observed by one of us.

Believing, as we do, that many cases with the symptom-complex known as Landry's paralysis are cases of multiple motor neuritis, we must seek a cause for the first manifestations of the paralysis in the lower limbs. The ingenious theory of Edinger may give us the answer. The nerves of the lower limbs are most employed, and therefore are most susceptible to poisons, and we have in Landry's paralysis, as in tabes resulting from another poison, the symptoms first manifested in the lower limbs.

*From the Department of Neurology, and Laboratory of Neuropathology in the University of Pennsylvania, and from the Ayer Clinical Laboratory, Pennsylvania Hospital. Read before the Philadelphia Neurological Society, April 24, 1906.

We have recently had an opportunity to observe three cases that might be classed as Landry's paralysis, two with necropsy, but we prefer to regard them as atypical forms of multiple motor neuritis, atypical in the rapidity of their development. Multiple neuritis sometimes develops very rapidly, and one of us (Dr. Spiller) has had recently in his service at the Philadelphia General Hospital a case in which complete paralysis of all four limbs with great tenderness of all the muscles of the limbs to pressure, developed in about twenty-four hours.

These three cases resemble one another closely in the rapidly developing motor paralysis. The sensory symptoms in the first two cases, in the opinion of some, would prevent the diagnosis of Landry's paralysis, but those sensory symptoms were much less pronounced than the motor. We have described the three cases together to show the common pathological basis. Sensory symptoms were not excluded by Landry. There is much confusion regarding what should be called Landry's paralysis, as shown by E. W. Taylor and J. E. Clark.[10]

In the first case (a man 52 years of age, a laborer, of good habits) the condition started with numbness in the right hand and slight disability. Twelve hours later the hands were paralyzed, the legs weak, while in thirty-six hours a complete paralysis of all four limbs had developed. The paralysis was accompanied by pain in the calves of the legs and in the shoulders. These pains persisted ten days. The patient was examined four weeks after the onset of the disease; at this time there was complete flaccid paralysis of both upper and lower extremities, with absence of deep reflexes. The muscles of the arms and calves and the ulnar nerve were slightly tender to pressure. The sensations of temperature, pressure, and pain were normal. Control of the bladder and rectum was preserved. The head was not involved; the eyegrounds were normal; there was no fever. The muscles showed no marked alterations to electrical stimuli. After several months a small amount of voluntary motion of all four limbs was regained.

In the second and third cases death occurred and the course of the disease was rapid.

The second patient was a man, 60 years old, who had been a moderate drinker; he developed a sudden paralysis of both arms and legs. There were no premonitory symptoms, the patient waking one morning to find himself helpless. This paralysis was accompanied by numbness, pain in the lumbar region which shot down the inner side of the thigh to the toes, and pain in the arms. There was dyspnea, inability to cough, and difficulty in starting urination. On admission to the hospital two days later there was complete paralysis of the upper and lower extremities and of the diaphragm. The deep reflexes were absent. Sensation was unimpaired in the upper extremities, but on the inside of the thighs areas of anesthesia were found to alternate with areas of hyperesthesia. The sensory symptoms were comparatively slight. The paralysis ascended rapidly. The shoulders became involved; the voice was lost; swallowing became impossible, until finally, four days after the onset, the patient suddenly had dyspnea and died. Just before death he had incontinence of urine and feces. There was no fever. The autopsy findings as regards the nervous system were entirely negative. There was chronic aortic endocarditis and chronic nephritis. Macroscopic and microscopic examination of the spinal cord and brain showed no lesions. The peripheral nerves were not obtained. Bacteriological examination proved negative.

The third case differs from the other two in that there were no sensory disturbances, which, however, were not intense in the other two cases. The patient, a man 60 years old, who had been a painter for fourteen years but had not had lead colic, felt one evening a heavy sensation in his legs. The next morning his legs were weak, and in twenty-four hours they were partially paralyzed. The paralysis rapidly ascended. In two days the arms were affected and there was difficulty in swallowing. There was no pain and no incontinence of urine or feces. He was admitted to the hospital five days after the onset, and showed then almost complete paralysis of both upper and lower extremities with loss of all the deep reflexes except for a slight plantar response. Sensations were perfect. The paralysis rapidly became more profound and ascending and involved the muscles of the thorax and shoulders. The voice was lost, swallowing became impossible, dyspnea developed, and on the eighth day after the onset there was sudden cyanosis and death. The temperature remained normal. At autopsy there was an acute bronchopneumonia and chronic nephritis. The brain could not be examined. The spinal cord appeared normal on macroscopic examination. A microscopic study showed slight but distinct degeneration of the internal plantar and one other nerve; extensive changes in the anterior horn cells of the lumbar region, and marked fatty degeneration of the gastrocnemius muscle. Again the bacteriological examination was negative.

Finally, in the last case, one of typical lead palsy, examination of the central and peripheral nervous systems showed extensive degeneration of the anterior horn cells in the lumbar and cervical regions of the spinal cord, with pronounced degenerative changes in the left brachial plexus and moderate degeneration of the ulnar nerve.

In the first case sensory symptoms were of short duration, whereas the motor symptoms were persistent; in the second case also the sensory symptoms were not very pronounced, and in the third case they were entirely absent throughout the course of the disease. The last of these three cases is one that belongs clearly to the group of Landry's paralysis, but the microscopical examination showed that the symptoms were caused by degeneration of the motor cells of the anterior horns of the spinal cord, of the motor fibers in the peripheral nerves, and of the muscles. This case is remarkable in that the recent degeneration of the muscles as shown by the Marchi method is intense and out of proportion to the alteration of the nerve cells of the anterior horns and to the degeneration of the nerves. To these three cases of motor neuritis, in all of which the paralysis of all four limbs developed within twenty-four or forty-eight hours, we have added the unpublished case of lead palsy, with necropsy, as an example of still another form of multiple motor neuritis.

To multiple neuritis also belong at least some of the cases of the neurotic form, or muscular atrophy.

The reports of these cases in detail are as follows:

Case I.—Gano, aged 52 years, was referred to one of us (Dr. Spiller) by Dr. D. W. Shelly of Ambler, Pa., and was admitted to the University Hospital February 27, 1905, when the following history was obtained: He has been a laborer all his life, working principally on a farm. He has been married twenty-two years; does not drink, smoke, or chew tobacco, and says he never has done so. He denies venereal diseases and has eight healthy children.

Four weeks previous to admission he first noticed numbness of his right hand about 6 P.M. He was unable to use his knife and fork properly at the sup-

per table that evening, with his right hand, but had no difficulty with his left. About the time he was ready to retire he found that the numbness was becoming more marked, and he was unable to unbutton his clothes. The following morning he could not use either his left hand or his right, and numbness was felt in both hands and arms. The lower limbs also were first noticed to be weak and numb, and he had some difficulty in walking and was obliged to hold on to the furniture as well as he could with his weak hands. On the evening of the same day he attempted to go upstairs and found that he was unable to do so. His legs gave way beneath him and he was obliged to sleep downstairs. That evening he began to experience dull and sometimes shooting pains in his calves, in his shoulders, and back.

The following morning he was completely paralyzed in all his limbs, but had no difficulty in urination. The pains continued ten days, after which they disappeared.

He has not had incontinence of urine, but urination is a little slow, and the bowels are somewhat constipated. He had severe diarrhea three or four days before the paralysis developed.

The notes of the examination soon after his admission are as follows: He draws up his shoulders very slightly, and the right a little more than the left. There is very little distention of the abdomen when he breathes deeply, and he seems to have paralysis of the diaphragm. Respiration is very shallow and is mostly costal in type. When he attempts to breathe deeply both sternocleidomastoid muscles contract. The upper limbs are completely paralyzed and flaccid. The skin of the hands is rough and desquamative, especially on the palmar surfaces. The biceps and triceps tendon reflexes are completely lost on each side. The sensations of touch, pain, and temperature are normal in both upper limbs and over the front of the trunk. The muscles of the upper limbs and the ulnar nerves are tender to pressure. Squeezing the hands causes much pain.

The lower limbs are completely paralyzed except that the man can draw each limb upward a little at the hip. The patellar tendon and Achilles tendon reflexes are lost on each side. Babinski's reflex is not obtained, the toes not moving in either direction from irritation of the sole of the foot. Both calves and feet are very tender to pressure. Sensations for touch, pain, and temperature are normal in the lower limbs and there is no distinct atrophy of these limbs.

March 6, 1905. The cranial nerves are not implicated, and sensation in the face is normal. The pupils are equal, and the pupillary responses are normal. The head is moved freely from side to side. The heart, lungs, and abdominal viscera seem to be normal.

Dr. de Schweinitz's examination of the eyes revealed nothing abnormal. Dr. Potts made an electrical examination and reported as follows:

"March 16, 1905. *Right leg:* All muscles respond to a strong faradic current (all but one inch of secondary coil) excepting peroneals and rectus femoris, which do not respond. *Flexor longus digitorum* requires somewhat weaker current than the other muscles.

"Left leg: All respond to strong faradic current, slightly better than those of right leg.

"Right arm: All muscles, also those of shoulder, pectorals, and abdominal muscles respond to strong faradic current, but not so strong a current is required as for the leg (secondary coil two inches from end).

"Left arm: All muscles respond to slightly weaker current than is required for the right arm.

"Right leg: Tibialis anticus, flexor longus digitorum, gastrocnemius, soleus, show quantitative decrease. K Cl C > An Cl C. No modal change. Peroneals quantitative decrease. An Cl C > K Cl C. Modal change. Rectus femoris, An Cl C > K Cl C. Modal change. Vastus internus, An Cl C > K Cl C. Other muscles of thigh, K Cl C > An Cl C. Tendency to modal change in adductors, irritability about normal.

"Left leg: In muscles below the knee, K Cl C > An Cl C. In soleus slight modal change, quantitative decrease. In vastus externus, An Cl C > K Cl C. Slight modal change in other muscles of thigh, no change in irritability.

"Right arm: K Cl C > An Cl C in all muscles, irritability about normal, excepting in ulnar distribution, where it is increased and An Cl C is relatively greater than normal.

"The same holds good for the left arm.

"With the faradic current the muscular contractions did not cause any motor effect. Galvanic current did cause motor effect in arms, but not in legs."

The patient did not have any fever, and after some months regained a small amount of voluntary movement in all the limbs, sensory disturbances having entirely disappeared.

Case II.—Dr. C. C., 60 years of age, physician, was a patient in the service of Dr. A. V. Meigs at the Pennsylvania Hospital. On admission he complained of paralysis of the arms and legs.

Family History: Father died of apoplexy, aged 84; mother died of old age at 88; one brother living, aged 63, has hemiplegia; one sister died recently from dropsy and hemorrhage from the bowel. Three daughters and one son living and well. One uncle died of apoplexy; one brother living and well, a minister.

Personal History: Had typhoid fever when 16 years of age; has had no other disease. Was graduated from the University of Pennsylvania Medical School in 1870, then practised in Virginia, later in Iowa, and for the last fifteen years in Philadelphia. Uses alcohol moderately; chews tobacco moderately; no drugs (?). Had lumbago, which stiffened his legs, about ten years ago. No venereal history.

Present Illness: About two years ago the patient awoke in the morning with severe "lumbago," which also passed around his waist and made his legs stiff so that he could not get out of bed. He also had pain in his hips and numbness in his feet. He was in bed with the attack four or five days and gradually improved. Since then he has had no trouble with his legs at all. Day before yesterday when he awoke in the morning he found that he could not move his arms or legs; he had been perfectly well the evening before, and can think of nothing he had done in the direction of unusual exertion, except a fall on his hip five days before. He has had since the onset a feeling as of pins and needles in his extremities, and pain in the lumbar region, which shoots down the inside of his thighs to his toes when he is moved. This morning he has had slight pain running down the inside of his arms. He has had no headache, loss of consciousness or convulsions. Bowels have not moved since the attack; has had slight difficulty in starting urination. There is dyspnea, inability to cough, but no dysphagia. He has had no trouble with vision. (Had a blow in his right eye in 1889 and three years later Dr. Harlan did a tenotomy; the eye has been blind since it was struck.)

Physical Examination: Patient is a large, well-

nourished man, lying on his back; slightly dyspneic, apparently employing only the upper part of his chest; abdomen retracts with each inspiration (no Lytton's sign); skin of trunk and extremities covered with an eruption consisting of small crusts, evidently arising from scratching. Urine: dark amber; mucoid sediment; acid, 1,028; no albumin or sugar; few hyaline casts. On the shins are three or four large pustular lesions covered by dark crusts. Right eye: (optic atrophy) has been blind for eighteen years; pupil small and immobile, internal strabismus. Left eye: pupil is eccentric, being nearer the lower part of the cornea; apparently it reacts normally. No facial paralysis; tongue slightly coated, protruded straight, no tremors. Movements of neck normal except that he cannot raise his head very high. He can flex the fingers slightly and extend the right leg slightly. He can also raise his shoulder. All tendon reflexes in the extremities are absent. No plantar reflex; no Babinski; tactile and pain sensations in the upper extremities are normal. There are irregular areas of anesthesia in the thighs, and in other areas there is apparently hyperesthesia. The patient complains of a great deal of pain in his hips. Lungs: anteriorly are normal. Heart: O. C. D. normal, sounds clear, regular and of fair tone. Liver and spleen: negative. Abdomen: negative.

January 22. Patient died yesterday about 4 P.M. About 2:30 P.M. he suddenly became exceedingly dyspneic and cyanosed. The pulse remained very strong and he was conscious until late. In the morning he was unable to raise his shoulders or to speak above a whisper, and complained of heaviness of his chest. At noon he was unable to swallow; had incontinence of urine; bowels did not move. Average temperature, 97; average respiration, 25; average pulse, 90.

Autopsy No. 652; Hospital No. 3,311. January 22, 1905. *Anatomical Diagnosis:* Chronic diffuse nephritis; chronic aortic endocarditis; cardiac hypertrophy; acute splenic tumor; cloudy swelling of liver; congestion of brain; congestion of viscera; rupia (?).

The body is that of a fairly well-built old man, 172 cm. in length. Rigor mortis well marked. Much purplish discoloration of dependent parts. Left pupil dilated, right contracted. On arms, chest, back, abdomen, and legs are numerous small, raised black scabs, averaging about the size of a pinhead and occasionally running into streaks. On the inner surface of the right arm, most marked at the elbow, are very small ecchymotic spots. Over the anterior surface of both tibiæ there are several large raised crusts, varying from 1 to 2.5 cm. in diameter. Six of these are on the right and one on the left leg, from which the scabs have been removed. The scabs are piled up towards the center, having a slightly purplish skin margin, which is dried and over which the epidermis scales off in concentric rings. External genitalia apparently normal. The abdominal fat measures 3 cm. in thickness and is orange colored. The muscles are rather pale.

Abdominal Cavity: The omentum is small and contains a good deal of fat. Peritoneal surfaces are smooth and glistening. The intestines are pinkish or gray in color and rather collapsed. Appendix measures 11 cm. in length, lies pointed upward behind the cecum in the retroperitoneal tissue, is patent to tip and apparently normal. The liver is bound to the diaphragm by fibrous adhesions. Diaphragm extends to third interspace on right side and to fourth interspace on the left side.

Thorax: The lungs are voluminous and meet in mid line. Both pleural cavities are free from fluid and adhesions. Pericardial cavity contains a small amount of clear, straw-colored fluid.

Heart: Weight, 390 grams. The heart is quite large, the cavities are filled with fluid blood and red post-mortem clots. The pericardium is smooth and glistening and contains a good deal of fat. The tricuspid and pulmonary valves are thin, delicate, and apparently normal. The mitral leaflets are also quite delicate; the aortic flaps, although large, are a little thickened and present calcified patches at the bases of the sinuses of Valsalva which stiffen the attachments of the leaflets. The heart muscle is firm, beefy, and red in color. The left ventricle is hypertrophied; the wall measures from 15 to 20 mm. in thickness, and the cavity is small. The aorta is large; the wall is not thickened, and the surface is exceedingly smooth. Coronary arteries are large and patulous. Auricular appendages are free from thrombi.

Lungs: The left lung is fairly large, rather heavy and soggy, especially in the posterior portion. The anterior portion of the upper lobe is lobulated, mottled dark gray, red, and black. Posterior portion of the upper lobe and lower lobe present a smooth, bluish-gray surface. The pleura is everywhere smooth and glistening. Lung is everywhere crepitant. On section cut surface oozes blood and frothy fluid, is deep purplish-red in color, soft and crepitant, except for a few indefinite red patches in the lower lobe. Bronchi at root are congested and contain bloody mucus. Vessels are clear. The right lung is in general like the left. The lower lobe is quite heavy and soggy. Crepitation, though present, is generally decreased. On section there is general congestion and edema, and one sees indefinite small solid patches in the lower lobe and a few more definite, raised, grayish, granular patches in the upper lobe. Bronchi and vessels at root are like right lung.

Spleen: Weight, 120 grams; measures 13 x 12 x 4 cm. The spleen is of medium size, regular, exceedingly soft and mushy. Color is a pale violet. The capsule is roughened and thickened in many places. Posteriorly it is firmly adherent to the diaphragm. On section the pulp is soft, almost diffluent and of a pale, muddy, red color. Malpighian bodies seem to be very large and indefinite; trabeculæ not very prominent.

Liver: Weight, 1,680 grams. Size, 26 x 18 x 10 cm. Liver is large, regular, and decreased in consistency. Capsule is adherent over a large portion of anterior surface to diaphragm and is torn in removing the organ. Color is a uniform light reddish-gray. On section the cut surface is smooth; the lobules are well marked, the centers being red and the peripheries gray, so that the surface has a slightly fine mottled appearance and is generally opaque and cloudy. Portal connective tissue is not specially increased. Bile ducts are patent. Gall-bladder is apparently normal.

Kidneys: Combined weight, 220 grams. The left measures 12 x 4.5 x 5 cm. It is fairly large, regular, and firm. The capsule strips with a little difficulty, leaving a finely granular, dark red surface showing a few injected stellate veins. Here and there, three small yellow points the size of a pinhead are seen. On section the kidney substance is decreased in proportion to the pelvic fat, but is still present in fair amount. The striæ are well marked, usually irregular, occasionally a little distorted. The medullary pyramids are large, dark, and streaked with purple. The cortex is from 6 to 10 mm. in thickness and is red in color. Vessels are injected. The glomeruli are large and purple in color. Pelvis and ureter apparently normal. The right kidney measures 12 x 6 x 3.5 cm. The surface shows two small yellow pits. In all other respects the kidney

is like the left. Adrenals are apparently normal. Testes apparently normal. Urinary bladder, prostate, seminal vesicles apparently normal.

Stomach and Intestines appear normal except for some congestion.

Brain: The brain is of medium size and fairly regular, although bulging a little over the parietal lobes. The dura mater is thickened and adherent to the pia in places. The pia is slightly thickened. The vessels are congested. At the base the vessels are very delicate and collapsible. The ventricles are not dilated. No macroscopic lesions are found.

Spinal Cord: Both the dura and pia mater are delicate; there are no adhesions between them. Vessels are congested. The general appearance is normal. On section the white matter seems very faintly mottled in many places by yellowish patches. This is irregular, but seems to affect most of the posterior portion of the cord. Left eye appears normal.

Aorta: The ascendnig arch is quite smooth; in the descending arch, about the opening of the greater vessels, there is an irregular, circumscribed patch about 2 cm. in diameter, which is yellow or cream-colored, raised, scarred, softened, and in some places calcified. Throughout the abdominal aorta there are localized, nodular, yellowish and cream-colored swellings varying from the size of a pea to 1 cm. in diameter; they are rather soft and have a fairly smooth surface. They are particularly numerous about the openings of the blood-vessels. Iliac vessels are free from thrombi. There is no general enlargement of the lymph nodes.

Microscopical Examination.—Heart: There is an excess of pigment about the nuclei of muscle fibers, with some fatty degeneration; no increase in connective tissue.

Lungs show marked congestion, and in places the alveoli contain large cells filled with brownish-black pigment, a little coagulated serum, red blood corpuscles, and polymorphonuclear leucocytes.

Spleen: The capsule is thickened and contains a good deal of yellowish-brown pigment. The pulp shows a patchy congestion, with general hyperplasia of the cells. The Malpighian bodies are large and in some the germinal centers are swollen and show central necrosis. There is some thickening of the intima of the blood-vessels.

Liver: There is well-marked congestion, with some parenchymatous and fatty degeneration of the liver cells. The portal connective tissue is slightly increased.

Kidney: There is much congestion, and the cortex presents slight proliferative changes. In the connective tissue descending from the capsule there are many small round cells. The tubular epithelium shows parenchymatous degeneration. Most of the glomeruli are engorged with blood; a few have undergone complete fibroid change.

Aorta: There is an extreme grade of irregular fibrous thickening of the intima, with fatty degeneration, deposits of cholesterin crystals and calcified material. The media suffers little change, though there is some degeneration of the elastic fibers.

Sections of the spinal cord, stained in hematoxylin and acid fuchsin (midlumbar and cervical regions). No definite alterations can be made out. The vessels of the pia and the smaller vessels of the cord are delicate and show no thickening. The cells of the anterior horns stain well by the thionin method, but are much pigmented. Marchi sections also are normal. Unfortunately peripheral nerves were not obtained.

Case III.—A. L., 60 years of age, painter; was in the service of Dr. A. V. Meigs, Pennsylvania Hospital. Complains of paralysis of arms and legs.

Family History: Father died of diabetes; mother of accident; two sisters have diabetes. No other family disease; no nervous disease. Has three healthy children.

Personal History: Has never been sick in his life, except for a few slight attacks of rheumatism. Had gonorrhea when about fifteen years old; never had chancre; drinks whiskey occasionally, but never to excess; never had lead colic; no injury in recent years (barrel fell on him many years ago). He has been a painter for fourteen years and at the onset of this attack was in perfect health.

Present Illness: Last Friday night (five days ago) patient noticed, while going upstairs, that he had a feeling as if heavy weights were in his hip pocket; also when he stooped down he had difficulty in rising. He slept well that night, and had no discomfort, but in the morning found that his legs were so weak that he could not stand to dress himself and he could put on only one of his shoes. By evening he could not raise himself because of weakness in his back. On Sunday his hands and arms began to be weak, and swallowing became difficult. Since then there has been no change except that the existing paralysis has become more complete. There has been absolutely no pain since the beginning of the attack. There has been no loss of sensation, or perverted sensation; no loss of control of the bladder or rectum. No dyspnea. Bowels have been moved by laxatives.

Urine: amber color, clear, acid, 1035; albumin, very faint trace; no sugar, few hyaline casts. Hemoglobin, 95. Leucocytes, 4,900.

January 24.—*Physical Examination.*—Patient is a fairly well-nourished old man, apparently no older than he is; speaks distinctly and intelligently; soon becomes tired of lying in any one position, but otherwise has no complaint. Pupils and movements of eyeballs are normal; no facial paralysis; can turn his head from side to side, but cannot raise it from the pillow. Tongue is protruded straight; some difficulty in swallowing, but he is able to get down liquids fairly well; is able to shrug his shoulders and can move his right arm a little, but grip with the right hand is very weak. Complete paralysis of the left arm; sensation as elsewhere apparently normal for tactile and pain sensations. Abdomen protrudes with each inspiration (Lytton's sign present); can extend the toes and move both ankles very slightly; plantar reflex present to a slight degree; no Babinski; both knee jerks absent; no ankle clonus; no apparent atrophy; control of bladder and rectum normal.

January 25. Had a restless night; swallowing difficult; paralysis about the same; voice not so strong as yesterday; no pain; much mucus in throat.

January 26. Sleeps very little, mind perfectly clear; voice weaker, sometimes whispering; grip of right hand is noticeably weaker; is fed from a medicine dropper; had to be catheterized for the first time this evening; no difficulty in respiration, but complains very much of the mucus which collects in his throat.

January 27. Cannot speak above a whisper today; had to be catheterized this morning, but later urinated involuntarily. Bowels have not moved since admission; cannot move his right hand this evening; about 4 P.M. became cyanosed and complained of dyspnea; also of pain in his legs, and the pain later moved to the small of his back. Entirely unable to swallow since noon; chest does not expand with respiration; diaphragm moves; slightly

irrational this P.M.; pulse weak and rapid; profuse perspiration.

January 28. Died at 10:10 P.M. For three hours previously had been semi-stuporous, but was able to answer questions; had to be propped up to get his breath; pulse very weak and rapid; breathing stertorous towards the end, but was regular; this suddenly became shallow and in less than a minute ceased entirely.

Average temperature, 99; respiration, 28; pulse, 90.

Autopsy. No. 653. Hospital No. 3378.

A. L. January 28, 1905; aged 60 years; performed by Dr. Longcope.

Anatomical Diagnosis. — Acute bronchopneumonia; congestion of liver, kidneys, and abdominal viscera; chronic interstital splenitis and hepatitis; chronic diffuse nephritis; chronic fibrous pleurisy.

The body is that of a well-developed man, 170 cm. in length. Rigor mortis is marked. Slight post-mortem discoloration over dependent parts. Pupils equal and dilated. External genitalia normal. No edema of extremities.

Abdominal Cavity: The omentum is quite large, contains a good deal of fat, and lies in the upper part of the cavity. Peritoneal surfaces are smooth and glistening, but slightly injected, mottled pink, and brownish yellow. The appendix measures 5 cm. in length hangs over the brim of the pelvis, is free, and the lumen is obliterated throughout. Diaphragm extends to the fifth space on the right side and to the fifth rib on the left side.

Thorax: Lungs are voluminous and collapse on removal of the sternum. The right pleural cavity is free from fluid and adhesions. The left pleural cavity contains cobweb-like fibrous adhesions. Pericardial cavity contains a slight excess of clear, straw-colored fluid; serous surfaces are smooth and glistening.

Heart: Weight, 240 grams. The heart is of medium size, epicardium is smooth and glistening, contains a good deal of fat, and shows at one point over the right ventricle a milk patch the size of a quarter. The vessels are prominent and the lymphatics somewhat dilated. Cavities are filled with soft, red post-mortem clots, but are not greatly dilated. All the valves are exceedingly thin, delicate, and normal. The endocardium is everywhere thickened and gray in color. The heart muscle is fairly firm, cloudy, and brownish-red in color. The left ventricle averages from 12 to 15 mm. in thickness. Coronary arteries are patulous and their walls are fairly delicate. The aorta is quite smooth and delicate except for a few yellowish cross-streaks above the aortic leaflets. Auricular appendages are free from thrombi.

Lungs: The left lung is large, rather heavy and soggy. Anteriorly the color is gray and the lung is lobulated. Posteriorly it is smooth and deep purplish in color. Over the apex the pleura shows small, thick, white cartilaginous areas of thickening, and in one or two other points there are similar patches two or three centimeters in diameter. There is some air everywhere throughout the lung. On section the cut surface is deep purplish-red in color and oozes frothy blood and serum. Scattered everywhere throughout the lower lobe are numerous small raised purplish-gray areas, slightly granular and firm; they average about 0.5 cm. in diameter. Bronchi at the root contain some bloody mucus. Vessels are clear. The right lung is rather small, somewhat retracted, and the pleura is covered with fresh fibrous adhesions, so that the lung is torn in many places during removal. The organ is heavy and contains very little air, the lower lobe being almost entirely solid, but at the same time rather soft and flabby. On section the lung presents a deep purplish-red, moist surface, from all parts of which bloody fluid filled with air bubbles exudes. The middle lobe and anterior portions of the upper lobe are crepitant. The remainder of the lung presents large, irregular, solid patches which are sometimes smooth and red, but more often raised, granular, and grayish. Between these areas of consolidation there is usually a little air contained in the lung. Bronchi at the root are congested and contain a little mucus. Vessels are clear.

Spleen: Weight, 90 grams; size, 10 x 7.5 x 4 cm. The spleen is small, regular, and much decreased in consistency. The color is pale lilac. Capsule is wrinkled, shows a little thickening, and is free from fibrous tags. On section the cut surface is a little rough, trabeculæ being coarse, increased, and prominent. The color is mottled gray and red. Malpighian bodies are quite large and pale.

Liver: Weight, 1,410 grams; size, 24 x 21 x 6.5 cm. The liver is of medium size, fairly regular, and quite firm. Over the anterior surface of the right lobe the capsule shows a scar-like area of thickening, about 8 cm. in diameter; this does not extend into the liver substance. There is also a little thickening over the anterior surface of the left lobe; elsewhere the capsule is delicate, although the surface is a little irregular. The color is a uniform brown. On section the cut surface is slightly granular, brown mottled with red. The lobules are well marked and regular, their centers are red, peripheries brown. Portal connective tissue is a little increased. Bile ducts patent. Gall-bladder is normal.

Kidneys: Combined weight, 250 grams. The left measures 12 x 5 x 4 cm. It is of medium size, regular and firm. The capsule is slightly thickened, strips with difficulty, leaving a finely granular, uniform purplish-red surface. On section the kidney substance is slightly decreased in proportion to pelvic fat. The medullary pyramids are fairly large, slightly irregular, and streaked with purple; cortex is deep red and well defined, is somewhat irregular and measures from 4 to 8 mm. in thickness. The striæ are well marked and regular; glomeruli are injected. Pelvis and ureter apparently normal. The right kidney is like the left. Adrenals are apparently normal. The urinary bladder contains several cubic centimeters of cloudy urine; mucous membrane is deeply congested and purplish-black in color about the trigonum. The prostate is large across the lateral lobes, which measure 5 cm. from right to left. On section it is soft and has a spongy appearance. Seminal vesicles and testes apparently normal. Pancreas is apparently normal.

Stomach is congested and shows hemorrhages on the crests of the rugæ.

Intestines are apparently normal. The *aorta* is quite smooth throughout the arch. In the thoracic portion just above the bifurcation of the iliacs, the wall is partly calcified, but thin, and the intimal surface is smooth. Iliac vessels are free from thrombi.

Spinal Cord shows some congestion of the pial vessels. The dura mater and pia are thin and delicate. There is a small amount of clear fluid in the arachnoid space, but otherwise normal to the naked eye. Muscles of the calf appear normal. Permission to open the skull could not be obtained.

Microscopical Examination. — Heart: Muscle fibers are small and show an excess of pigment about the nuclei. There is some increase in the connective tissue of the large trabeculæ.

Lungs show marked congestion and edema, with patches of bronchopneumonia where the alveoli are filled with leucocytes, red blood corpuscles, and a little fibrin.

Spleen shows a patchy congestion, with some increase in the connective tissue of the pulp. The Malpighian bodies are large and their margins ill-defined. There is some thickening of the intima of the blood-vessels.

Liver shows some congestion, with parenchymatous degeneration of the cells.

Kidney shows slight increase in connective tissue of the cortex, with swelling and parenchymatous degeneration of the cells of the convoluted tubules. The glomeruli are as a rule congested. Many hyaline casts are seen. The intima of the blood-vessels presents a moderate grade of thickening.

Bacteriological Examination. — Cultures made by Dr. Robinson from the left lung yielded *Micrococcus lanceolatus* and an unidentified bacillus. Cultures from heart's blood showed no growth after forty-eight hours at 37° C.

Spinal Cord. Lumbar region: The sections appear to be normal except that in many of the nerve cells of the anterior horns the chromophilic elements have become granular and the nucleus is displaced to the periphery of the cell. The alteration of the nerve cells is distinct, but not intense. The pigmentation of the cells is pronounced. The anterior and posterior roots are normal. Cervical swelling: The condition of the spinal cord at this level is much the same as in the lumbar region. No alteration is seen by the Marchi method. Sections of the sciatic nerve are normal. Pieces of the right obturator, internal plantar, and posterior tibial nerves were examined, but the portions of nerves removed had become mixed. In two of these smaller nerves some degeneration is observed by the Weigert hematoxylin stain. Slight but distinct degeneration in the form of many black granules is found in the right internal plantar and the left internal popliteal nerves when fibers are teased in the fresh state and stained by osmic acid. Swollen axis cylinders are seen in one of the small nerves. When a nuclear stain is employed the muscle appears normal, except that there may be a slight increase in the sarcolemma nuclei. Nerve fibers within the muscle are normal.

Case IV.—J. L. A., 67 years of age, was at first in the service of Dr. Alfred Stengel, at the Philadelphia General Hospital, and was then transferred to the service of Dr. Spiller.

July 16, 1904. He had been a painter since he was 14 years of age. He first began to have weakness with his upper limbs in 1876, and has had six or seven attacks (probably of paralysis) in these limbs since. Two weeks ago he stopped work, complaining of diarrhea and loss of power in his upper limbs. He has not had headache nor pain anywhere. Has lost his appetite. He could walk when he had his shoes on without much difficulty. He is emaciated and anemic, and his face appears edematous. Pupils are equal and react sluggishly. He has no blue line on the gums. Pulses are equal and easily compressible; vessels do not show much sclerosis. Chest is somewhat emaciated, supraclavicular spaces are sunken, interspaces are wider than normal. Lungs are resonant and no râles are detected. Rough breathing is heard over the anterior surface of the right lung at the upper part. Heart dullness is about normal in outline; sounds are not very strong; no murmurs. Liver dullness extends from the upper border of the sixth rib to two fingers' breadths below the costal border. Spleen not palpable. Epigastric pulsation is marked.

He has bilateral wrist drop, with much atrophy of thenar and hypothenar eminences. In the lower extremities there is palsy and atrophy of the peroneal groups of muscles. The skin of the feet and legs is glossy, and there is some swelling and pitting upon pressure. He shows a marked intention tremor of the hands. Patellar tendon reflex is diminished; biceps tendon reflex seems to be normal. He has not had any pain or disturbance of vision.

August 15, 1904. He is very feeble, and examination is unsatisfactory because of stupor. He does not obey commands. He moves his head freely from side to side; does not take his nourishment now, but has not had any difficulty in swallowing. The wrist drop is very pronounced on each side, but he is not paralyzed in the muscles of the shoulders, as he can voluntarily place both upper limbs above his head. The fingers of each hand, especially those of the right hand, are somewhat cyanotic. The biceps tendon reflex is weak on the left side and uncertain on the right. The triceps tendon reflex is not obtained on either side. The muscles of the arm of each side are wasted, but not so much as those of the forearms. Each forearm and each hand are much wasted, but the extensors on the back of the forearms are more wasted than the flexors. He has not been seen to move his lower limbs, although he has some power in the muscles of each thigh. The lower limbs are flaccid except at the ankles. The feet are in the position of talipes equino-varus and cannot be passively straightened. The lower limbs are much wasted, especially in the peroneal group of muscles. The patellar reflex is entirely lost on each side. Achilles tendon reflexes cannot be obtained. Babinski's reflex is uncertain on the right side, there being no distinct movement of the toes on account of the contractures. This reflex cannot be tested on the left side, because of an amputation at the metatarsophalangeal articulations. He has incontinence of urine and feces. His mentality is much obtunded.

Pathological Diagnosis.—Brown atrophy of heart, senile emphysema, chronic interstitial nephritis.

Microscopical Examination. — Lumbar Region: The nerve cells of the anterior horns are much altered; the chromophilic elements in most of the cells, instead of being rod-shaped, appear as fine granules. The posterior and anterior roots are normal. There are no signs of meningitis. No degeneration can be detected by the Marchi method.

Midthoracic Region: Sections from this region present no secondary degeneration of the posterior columns, and the posterior roots at this level are normal.

Cervical Region: Sections stained by thionin show disintegration of the chromophilic elements like that of the lumbar region. Outside of the changes in the nerve cells, sections of the cervical region seem to be normal.

Paracental Lobule (left and right): The cells of Betz show slight disintegration of the chromophilic elements and much pigmentation, but on the whole the nerve cells are in a fair state of preservation. The proliferation of the endothelial cells covering the pia is not distinct in this case as it was in the former case of lead poisoning reported by one of us (Dr. Spiller), although a slight indication of it is detectable.

Left Brachial Plexus: Sections here show a pronounced partial degeneration both by the Weigert hematoxylin and acid fuchsin stains, but there is no degeneration by the Marchi method.

Pieces of the right ulnar nerve and of the left brachial plexus do not appear much degenerated by

the 1 per cent. osmic acid stain. It is unfortunate that more peripheral nerves were not obtained.

DIET IN TUBERCULOSIS.*

By HERBERT MAXON KING, M.D.,

LOOMIS SANATORIUM, LIBERTY, N. Y.

From time immemorial, the human race has paid its tribute to consumption, and it is fairly certain that from the start a proportion, sometimes great and sometimes small, of those affected, have been able by conscious effort or otherwise, to throw off the disease and recover. It is equally safe to assert that where this has occurred it has always been primarily by virtue of an improved nutrition—however accomplished.

There is a very general impression to-day, not confined to the medical profession by any means, that if we "build up the patient the disease will take care of itself," and it is also generally conceded that the requisites to this building-up process are essentially —good food, pure air, and proper rest. Other factors there are, to be sure, which may contribute toward the desired result—climate, light, water, drugs, etc., but they are of secondary importance.

So far then, the problem seems easy of solution, and it is not surprising in view of the apparent simplicity of the prescription, that the question is sometimes asked: "Why, then, if this is all that is required, do not more consumptives recover?"

But is the prescription after all so simple as it appears? What is *good* food? Is there such a thing as a *standard* diet? Will the same relative proportion of proteids, fats, and carbohydrates which serve so well with A be equally productive of good results in B? Is it merely a question of calorific values? The same with air; which may be equally pure at sea level or at an altitude of 5,000 meters. Where can pure air be found which will be most efficacious for the consumptive? What degree of relative moisture is most desirable? And have we any standards of pure air applicable to all consumptives alike, or even to all of a single class? Again with rest: How far should we carry restrictions as to exercise? Under what conditions can rest be most advantageously secured? Is there not a very real danger of falling into the thraldom of routine in our practice with regard to rest for the tuberculous invalid?

These are some of the many questions which I fear have not received that scientific scrutiny which characterizes so much in modern medicine.

In combating tuberculous disease, the means at our disposal are of a necessity limited, and for this reason if for no other, it would seem that they should be applied with all the more care and circumspection. Yet I am of the opinion that nowhere else in the practice of medicine is there a more extravagant or indiscriminate misuse of the means at hand than we are forced to see in the prescriptions for good food, pure air, and proper rest which are given to the consumptive patient "to apply as required" upon his own initiative. It is, as it were, to tell a patient with syphilis that mercury is a cure for his disease and leave to his own untrained and imperfect judgment the selection of the preparation, the dosage, and the mode of administration.

We must not forget that in such a matter as that of diet, while there is no doubt a standard of excellence, it is an *individual standard* rather than a *class standard* and must be worked out with as many variations almost as there are patients, if the best results are to be obtained. One patient may do well and recover on the coarse fare of a Canadian lumber camp, while another's success may depend upon the most cunning exercise of the culinary art.

But, although it may not be possible to formulate a dietary acceptable as a standard for tuberculous invalids as a whole, there should be no difficulty in agreeing upon certain fixed principles generally applicable and which should serve as a basis upon which to build the group or individual dietary.

For instance, we should arrive at some definite conclusions regarding the food requirements of the organism in the presence of certain pathological conditions and under identical climatic influences. We should determine the amount and relative proportions of proteids, fats, and carbohydrates per kilo of body weight required to nourish properly the consumptive whose disease is in abeyance and whose weight, temperature, and pulse are normal. Of course such a standard could serve only as a working basis. The real difficulties of the problem follow, for it is one thing to determine what the system requires and quite another to know how best to supply it in a form to be available to the tissues.

But even a working basis, however limited, its application, would be an improvement over the present chaotic state of our information with regard to diet in tuberculosis. Consider in what manner we are in the habit of advising our patient in this respect. We have explained to him the nature of his malady, and have exhausted our eloquence in impressing upon him the vital necessity of hyperalimentation as the primal factor in combating his disease. We have given him a list of foods which he must take in addition to three generous meals a day. Safe to say at the head of this list are the ubiquitous milk and raw eggs, to be consumed in as large quantities as the patient can manage! We have advised that he eat meat three times daily, take large quantities of fat, and limit his vegetables chiefly to those of a leguminous nature. This prescription for a dietary, and you know I have not exaggerated, reminds one of the original Warburg's tincture; something out of the whole ought surely to hit the mark, and if the patient can survive the effects of the balance he ought to get well.

A case in point came under my observation not long ago. It was that of a young man of twenty years. For a month previous his diet had consisted of three hearty meat meals a day, and in addition he had taken three liters of milk and twenty raw eggs, every twenty-four hours. I asked him if his physician had ordered this and he replied: "No, not exactly, but he told me to eat all the meat I could and to take as much milk and as many raw eggs as I could stand besides; and I found I could not stand any more than this without vomiting!"

*Read before the National Association for the Study and Prevention of Tuberculosis, at its Second Annual Meeting, held in Washington, D. C., May 16-18, 1906.

He had gained something like nine kilos (twenty pounds) in weight during the month, but as may be imagined, his digestion was hopelessly ruined and in the course of time he died. Roughly estimated, this young man was daily taking into his stomach 375 grams of albumin, 350 grams of fat, and 500 grams of carbohydrates, representing a total of 6,842 calories. I regret to say that I do not think this a very unusual instance, but it well demonstrates the unwisdom of open prescriptions and illustrates the grave danger of leaving a tuberculous patient to his own initiative.

Much good work has been done in the study of food metabolism, with a result of determining approximately the amount of food necessary to maintain good health in a normal, adult human being. Represented in calories, the generally accepted standard is thirty to thirty-five calories per kilo of body weight while at rest, and about forty calories per kilo of body weight for an individual under the ordinary conditions of life.

The relative proportions of the classes of food stuffs going to make up this number of heat units are theoretically, proteids, twelve; fats, five; and carbohydrates, fifty (Voit's Standard). However, not only the relative proportions but the daily total of food must necessarily vary with varying conditions, both of the individual and of his environment, and these conditions are so manifold and complex when it comes to treating the tuberculous invalid, that it becomes at once apparent how impossible it is to arrive at any specific standard of diet generally applicable in the presence of this disease.

Moreover, it is very doubtful if the last word has been said as to the food requirements of a healthy human being. I am inclined to believe that we have been making a fetich of proteids and fats and have paid too little attention to the carbohydrates.

A good digestion, of course, simplifies the problem. Given a sufficiently generous diet, nature will attend to the demands of the organism. There need be no anxiety as to the relative proteid, fat, and carbohydrate content of the ingested food, and in such cases the appetite alone is a sufficient criterion.

A good digestion, however, is rather the exception than the rule. Digestive disturbances are the most common antecedents of tuberculosis, and are apt to continue as harassing complications throughout the course of the disease. Thus with a poor digestion and assimilation, it is of the greatest importance not only to ascertain approximately the digestive capacity of the individual for the several elements, but to avoid overfeeding, either in total quantity of food or excess of any constituent element. It is often astonishing what can be accomplished with a little patience and study in improving nutrition in a dyspeptic consumptive, simply by judicious restrictions and tentative modification of relative proportions of ordinary food constituents. On the other hand, the results of most painstaking effort are not infrequently disappointing and discouraging, and, without being able to ascribe a cause, we may be forced to see a patient continue to lose weight and strength even while ingesting an amount and variety of food more than sufficient to sustain a robust working man.

Such a case recently came under my observation at the Sanatorium:—A woman, thirty-four years of age, weighing 62.302 kilos (137 1-16 pounds), with a barely demonstrable incipient lesion of the right apex, no bacilli in the very scant expectoration (they had been demonstrated, however, a month before), no elevation of temperature, and a normal pulse. The estimated normal weight for a woman of her height and years was 62.7 kilos (138 pounds), but a year prior to her admission she had weighed 71 kilos (156 pounds). She was thus considerably under her maximum weight. Her appetite and digestion were apparently excellent, her bowels and kidneys functionated normally, and she was not homesick. During a residence of three months, however, she continued persistently to lose weight, although not in large amounts, and this on a diet which was varied from time to time, but which averaged over 3,000 calories per day, or 48 calories per kilo of the patient's body weight.

The daily food régime in this case was about as follows, estimating the amount consumed:—*Breakfast* 8 A. M.: Cereal, two eggs, two glasses of milk, one slice of bread or toast; *Lunch*, 10.30 A. M.: Egg-nog, made with two eggs; *Dinner*, 1 P. M.: Soup, roast, two vegetables, salad, desert; *Lunch*, 3.30 P. M.: Egg-nog, made with two eggs; *Supper*, 6 P. M.: Cold meat, bread and butter, two glasses of milk, fruit; or approximately 130 grams albumin, 156 grams fats, and 260 grams carbohydrates. It will be noticed that these proportions vary somewhat from those usually indicated for healthy individuals under ordinary conditions of life in that the proteids are slightly increased, fats greatly increased (more than three times the amount called for in Voit's Standard), while the carbohydrates are diminished relatively about 50 per cent. Yet I believe that this diet comes nearer the average prescribed for the tuberculous invalid with a quiescent lesion than may be supposed.

During the fourth month of this patient's sanatorium residence, a rather radical change was made in her dietary with a view of checking the weight loss. Proteids were cut down to less than 120 grams and fats were reduced not to exceed 60 grams per day. This was largely accomplished by substituting skimmed for whole milk and by cutting out the yolks of eggs. At the same time, the carbohydrates were greatly increased, an effort being made to reach 500 grams per day and thus more nearly approximate the regulation standards. The results, however, were not very flattering. Further loss was, to be sure, checked, but on discharge at the end of the fourth month the patient had gained back but two or three hundred grams of the three kilos lost during residence; yet in this case the patient *felt well*, enjoyed her food, and apparently completely overcame the pulmonary lesion.

In rather striking contrast to this is the following case:—A girl, seventeen years old, with an extensive lesion and cavity in the right lung and a considerable area of infiltration deposits in the left lung, daily elevation of temperature, accelerated pulse, appetite poor, digestion and elimination fairly good, distinctly an infirmary case; notwithstanding which this patient made very satisfactory gains in weight, on a diet representing only 81+ grams albumin, 102+ grams fats, and 215 grams carbohydrates, a total approximately of 2,315 calories, or as the patient's weight was 43.5 kilos, 53.2 calories per kilo.

At the same time, in an adjoining room in our infirmary, a young woman, with a very similar pulmonary condition and constitutional reaction, but with some digestive disturbance, rapidly lost weight on a diet averaging 106.4 grams albumin, 128 grams fats, and 215 grams carbohydrates, a total approximately of 69.5 calories per kilo of the patient's body weight.

Of course it is not merely a question of the amount and latent heat value of fuel put into the furnace, but of even greater importance, the completeness of the actual combustion upon which depends the total of energy derived.

The theoretically ideal diet utterly and inevitably fails to accomplish its purpose when there is not the power to metabolize it to the requirements of the tissues. Indigestion, malassimilation, defective elimination, whether dependent upon psyconeurotic causes or upon profound organic changes, bring about one and the same result so far as body nourishment is concerned, and this is what makes the real problem of nourishment in the consumptive patient.

Suppose we have ascertained by experiment that an individual can metabolize satisfactorily 100 grams albumin, 50 grams fats, and 200 grams carbohydrates daily, but cannot exceed this amount without giving rise to more or less disagreeable symptoms. While we may be perfectly aware that this total falls below prescribed standards and may not suffice to produce phenomenal weight gains, I am strongly of the opinion that in the long run better results will be obtained from this small diet than will follow a stuffing process with a diet two or three times beyond the individual's capacity for metabolism. Hyperalimentation may be an excellent practice in certain cases under constant skilled supervision, but indiscriminately applied it is capable of working irreparable mischief.

The tuberculous patient, with a quiescent lesion and good digestion, like the healthy individual, undoubtedly eats more than his body actually requires, but here nature takes care of the unused residue and no harm ensues. Not so, however, in the consumptive with an active lesion and a tendency to digestive disturbance. Here unabsorbed food products and such as have been incompletely broken up become an actual menace in the alimentary canal and too often are responsible for the most serious complications.

In the institution, experience and a little common sense soon work out a very satisfactory mixed diet applicable to the average patient presenting a favorable prognosis, such as are admitted to most sanatoria. This, I confess, is usually accomplished without recourse to scientific research.

With a view of establishing a working standard so to speak, for certain classes of tuberculous invalids, the following experiment was recently made at the Annex of the Loomis Sanatorium:—

Twelve patients, equally divided as to sex, were selected with reference, first, to similarity of pulmonary condition, all but one with quiescent or arrested lesions, and that one with but a very moderately active lesion. Second, with reference to similarity of weight, the men, represented in the table following by 1 and 6 inclusive, averaging 11 or 12 kilos more than the women, represented in the table by the numbers 7 and 12 inclusive. And third, with reference to a close approach of each patient to his or her normal weight. It will be noticed, that in all but one case, the patients were slightly below the indicated standard. Nevertheless the appearance was that of a very well nourished group of individuals.

These patients were placed at a table by themselves, and their food, while not differing from that of the other patients, either in quality or quantity, was accurately weighed and recorded for a period of fourteen days.

The test patients' net weights were ascertained after breakfast in the usual manner employed at the Sanatorium, at the commencement of the test and again at its close. The urine and feces were weighed and superficially examined during the test, but as it was not practicable at the time to do certain work with the feces which alone could have made the observation valuable, the feces record has been omitted. In the case of the urine, the twenty-four hour amount, specific gravity, and total solids were estimated and recorded; but no exhaustive analyses were attempted, and thus the records have no value as indicating the proteid metabolism or nitrogen output, except in a most general way. At the close of the experiment the food actually consumed by each individual was totaled in its several constituents and separated into its albumin, fat, and carbohydrate content respectively. From these totals daily averages were ascertained. The fuel value, estimated in terms of large calories, was also recorded. It is here necessary to explain some minor discrepancies which may be noticed between the calorific values in the following tables.

Authors differ somewhat in estimating the heat-producing value of various articles of food, and instead of following the plan of working out each item separately I have, whenever possible, taken the calorific value as given in the work most convenient to hand at the moment. Chiefly, I have had recourse to the excellent tables compiled by Atwater and Bryant, and published at the Government Printing Office. These tables are undoubtedly the most reliable of any available for use in this country, although they differ often considerably from the German and French tables, probably owing to the difference in food composition and methods of cooking. But in some instances I have employed tables of other authors, and as the figures obviously can be no more than vaguely approximated, I have not deemed it necessary to reconcile them.

The following menu represents an average of that employed during this experiment, and does not differ materially from the food régime of the Annex of the Sanatorium during the past winter. It may be of interest to note that this dietary has cost the institution, during the past six months, on a basis of forty patients, 35 cents per patient per day, about one-third of the cost of the more elaborate dietary provided for the patients in the main division of the Sanatorium, yet of about the same practical value:

MENU.

BREAKFAST—7.30 A.M.

													763 gms.				58.49 gms.

It will be seen by reference to the table that eleven of the twelve patients made satisfactory, though not phenomenal gain in weight, averaging 763 grams (about 1 pound 10 ounces) per patient. So far as calories per kilo of body weight are concerned, it will be noticed that Patient Twelve, who lost 680 grams during the experiment, was consuming about the same as Patient Two, who made a gain of 115 grams.

On the other hand, Patients One, Seven, Ten and Eleven, who consumed about 80 calories per kilo of body weight, averaged a gain of 712 grams, while Patients Two, Four and Nine, who consumed under 55 calories per kilo, averaged but 227 grams, and Patient Twelve, who as above remarked, fell below 50 calories per kilo, lost 680 grams.

The total solids in the urinary excretion follow roughly in each case the amount of the proteid in the food consumed, and in so far indicate that about the same relative proportion of albumin ingested was metabolized by each patient.

On the whole, this dietary has seemed to us to meet, in a fairly satisfactory manner, the requirements of the class of tuberculous invalids treated in the Annex division of the Loomis Sanatorium. Nevertheless, I have felt that the proteid constituent in the dietary has been in excess of the tissue needs, and, if so, that an unnecessary and perhaps harmful tax was thus imposed upon the organs concerned in proteid metabolism and elimination.

If, as Folin has so ingeniously suggested (*New York Medical Journal*, March 3, 1906), the urea output does not at all, or but slightly, represent tissue catabolism, but, on the contrary, merely the unused and consequently superfluous product of metabolism of the proteids of the food, then it is obvious that whenever urea excretion is considerable, the proteid constituent of the diet is in excess of the body needs, and it is well known that in quiescent cases of tuberculosis on heavy proteid diets, the urea excretion exceeds the average for a healthy person under the ordinary conditions of life, just as occurs in the normal individual under otherwise similar circumstances. This is certainly a matter deserving further inquiry.

A further experiment was undertaken at the Sanatorium Annex, with a view of determining the effects of a diet rich in carbohydrates and relatively poor in proteids, as compared with a heavy proteid diet, poor in carbohydrates. But, as the plan adopted in this experiment could not be satisfactorily carried out in the time intervening before the date of this meeting, I cannot at this time report upon it.

Generally speaking, a tuberculous invalid without acute symptoms may be given a properly proportioned diet of from 45 to 80 calories per kilo of body weight, without danger of overfeeding; but one must exercise vigilance, for there are many exceptions to this general rule. For instance, I have a patient who does well and gains weight upon about 2,500 calories per day, divided as follows:—88 grams albumin, 129 grams fat, 197 grams carbohydrates; but whenever I have attempted to increase this diet I have been met by digestive disturbance and weight loss. In this case the diet represented about 48 calories per kilo of the patient's weight.

Phenomenal weight-gains in patients who have come under treatment greatly underweight, satisfactory as they are to the patient and to his family, should at once arouse a suspicion of overfeeding; an investigation in such cases not infrequently discloses the fact that the diet is approaching 100 calories per kilo, which is certainly a danger point, however well the patient may look and feel for the time being. In acute cases with high temperatures and rapidly destructive lesions, a heavy proteid diet is quite as much out of place as it would be in typhoid fever. Yet nourishment must be supplied if we expect to change the type of the process. It is in such cases that an almost exclusive milk diet best serves the purpose—raw, cooked, or variously modified, milk is the food with the widest range of useful-

ness in these cases. Three liters of whole milk, divided into unequal portions, the largest to be given at ordinary meal times, can be taken by most patients without inconvenience every twenty-four hours, and represent 99 grams of proteids, 120 grams of fat, and 150 grams of carbohydrates, or 2,137 calories. This is, of course, insufficient for the body needs in such cases, and will not prevent weight loss but it will check it, and will give the organs concerned in digestion, assimilation and elimination, the least strain at a time when it is most urgent to save the patient all unnecessary expenditure of energy.

As the type of the disease changes, which fortunately it does more often than might be expected, this milk diet must, of course, be supplemented and gradually superseded, for it cannot with safety be indefinitely continued.

In advanced cavity cases much underweight and without appetite but without acute symptoms, the ordinary three or four meals a day will not serve. Such patients cannot or will not undertake the effort of eating a sufficient amount, however attractively it may be served from the regular trays. It has been our custom, in the infirmary of the Loomis Sanatorium, in such cases to substitute a two-hour diet for the regular meals. The following is a fair representation of such a dietary and answers the purpose very well. It is subject, of course, to more or less daily modification to meet the whims and tastes of different patients or of the same patient on different days.

10 P.M.—Milk	190	6.27	7.60	9.50	136.23
Total	1,794	127.71	254.83	221.85	2,644.07

It will be seen that such a dietary for a patient weighing about 45 kilos (100 pounds) is equal to slightly over 60 calories per kilo of body weight. In such cases as would require a two-hour diet of this kind, I do not believe it wise to increase the proteid constituent, nor do I think anything is to be gained by increasing the fats; but when weight gain is not forthcoming after reasonable trial on such a diet, the carbohydrate constituent may be gradually increased to 350 or 400 grams, and if well borne by the patient will very likely result in weight gain and generally improved condition.

The nitrogen content of the urine alone is not a safe indication of the metabolism of the proteids of the ingested food, especially in the presence of a pathological process, such as a more or less active tuberculosis; for, as a rule, in direct proportion to the activity of the disease process the nitrogen output is increased, and thus it is not infrequent to find in the urine of such patients much more than sufficient nitrogen to represent the complete metabolism of all of the proteids ingested in the food. Of course, the excess at least must represent tissue catabolism.

I am not aware that much has yet been published on this subject with especial reference to tuberculosis. Investigation to be of value here involves a more tedious and painstaking study of the feces in connection with the urine and food than is often convenient to make. Yet it seems to me the matter is of sufficient importance to justify thorough research.

Recently four infirmary patients, whose condition indicated a two-hour diet like that described, not only failed to gain, but actually lost weight in a two weeks' trial, notwithstanding that in each case the diet represented over sixty calories per kilo of body weight, and that the nitrogen content of the urine represented on an average the metabolism of over 86 per cent. of the total proteids of the food ingested. I give in the following table the individual record of these four patients.

Case.	Av. daily proteid consumed—grams.	Av. daily urea output—grams.	Estimated av. daily metabolized proteids in urine—grams.
1	127.71	33.80	136.50
2	127.71	23.40	94.00
3	127.71	23.00	92.50
4	127.71	30.00	120.00

It will be seen that in Case I of this group the nitrogen content of the urine indicated the metabolism of actually more proteid than was contained in the food, and Case IV almost an equal amount, yet this latter patient was without fever or other symptoms indicative of activity, although much underweight and with a very extensive lesion.

In all of these cases, if a careful examination of the feces had been practicable, it would no doubt have shown that not sufficient proteids had been metabolized from the food to give a plus nitrogen balance, notwithstanding the generous allowance ingested. In view of such experience, one is tempted to accept the conclusions to be drawn from the remarkable experiments of Professor Chittenden, and to apply them to the tuberculous invalid. But much as I incline to the view that we have rather overestimated the value of proteids in tuberculosis, the question has not yet been sufficiently studied to justify any very radical departure from accepted methods.

It is quite impossible within the prescribed limits of this paper to consider in detail the many and various phases of the diet question as applied to the tuberculous invalid. It is certainly more than a question of calories, and it cannot be solved merely by arriving at theoretical standard amounts and relations of proteids, fats, and carbohydrates.

The tastes, habits, and peculiarities of individuals, even their heredity, are important factors. Variety, preparation, and the manner of serving of foods are matters which have a bearing upon the success or failure of the treatment, and the psychotherapy, which must and does enter into all successful treatment of the consumptive, is more important in diet prescriptions, perhaps, than anywhere else. Every patient, and for that matter every physician, has his prejudices, one might almost say his "fixed ideas," regarding diet, many of which are founded upon insufficient bases of fact, and in proportion as they are stubborn and difficult to eradicate, they increase the complexity of the problem.

One patient declares that he cannot drink milk. Another that he cannot swallow an egg. A third with an absurd uric acid phobia, insists that he cannot eat red meat. Fried foods are almost universally condemned, and our good friend, the pig, is fairly ostracized from good society in dietetic circles. I cannot but feel that in many cases these prejudices

are ill-founded. Do not let us forget that the staunchest and sturdiest set of men and women which this country has ever produced have been raised to healthy maturity and have withstood the vicissitudes of disease and an ungentle climate, on a diet of fried salt pork, potatoes, beans, and breadstuffs, with fresh meat perhaps once a week. Fried sausage and buckwheat cakes with maple syrup for breakfast carried no suggestion of dyspepsia to these good people, and they grew stout on apple-pie and doughnuts, regardless of the question of proteids, fats, and carbohydrates. But those good old days are no more, and even the New England farmer now inclines to a more critical attitude toward his food. He demands more meat, and there is no doubt that he has increased by nearly double the proteid content of his dietary. The question is, "Is he a healthier animal for the change?"

Of all dietic or medicinal agents employed in the treatment of tuberculosis, I believe there is none upon which more contradictory opinions and prejudices exist than is the case with alcohol. Even medical views upon this subject vary all the way from stern and uncompromising prohibition to extreme license.

It seems to me that in this, as in all else therapeutic, arbitrary extremes may be fraught with danger from that of failure to employ a most valuable aid to cure on the one hand, to that of fatal abuse of it on the other.

I am aware of the danger of being misunderstood in expressing an opinion indicating a middle course with regard to the use of alcohol in tuberculosis. Nevertheless, my experience leads me to hold such opinion. If the patient is doing well, has a good appetite and digestion, and is gaining weight satisfactorily without alcohol, certainly there is no excuse for prescribing it. But, on the other hand, where there is a tendency to anorexia, where digestion is sluggish, especially where milk is ill borne, where weight gain is not satisfactory, and, of course, where there is no specific contraindication, I know of nothing else that will quite take the place of some of the light wines or malt liquors in promoting the building-up process for which we are striving. In such cases it is both a food which is immediately available to the tissues, and a mild and harmless stimulant to digestion. It must be taken in moderation, that goes without saying, but the dosage which may with propriety be employed will vary within wide limits in different individuals, depending upon temperament, education, and idiosyncrasy.

As a general rule, to which of course there are many exceptions, light clarets, Rhine wines, or even Burgundy, may be advantageously permitted with midday and evening meals. To this list may be added the malt liquors, which are often preferred by patients, and such prescription need not in the least interfere with between-meal diets of milk and eggs. On the other hand, frequently the latter are much better borne when wine or beer constitutes the only beverage at mealtime. Distilled liquors have a much narrower field of usefulness in the dietetics of tuberculosis, but are permissible in certain cases when alcohol is indicated and the more bulky forms are ill borne. In such cases there is little or no choice as to what kind shall be used other than is indicated by individual taste, but whatever is used should be well diluted.

Roughly estimating, I should think I have prescribed alcohol in some form as a dietetic measure in from 5 to 10 per cent. of the tuberculous invalids under my care for the past fifteen years, and I confess I have never seen harm come from it in a single instance, while, on the other hand, I am sure that in many cases it has rendered invaluable service.

It would be little less than childish in this company to enumerate the many moral and physical contraindications to the use of alcohol in the manner I have suggested. The physician who prescribes it without a thorough knowledge of his patient from every point of view is bound to meet with disastrous results occasionally. But employed judiciously and with watchful individualization, alcohol has a definite and well-merited place in the dietetics of tuberculosis.

(It is not within the scope of this paper to consider the subject of alcohol as a medicine, and what has been said applies wholly to its employment in the *dietary* of the consumptive.)

In conclusion, one is forced to admit that in this matter of food for the tuberculous invalid, our teaching, up to the present time, has been largely empirical. Weight gains have followed heavy feedings, consequently the diet should be pushed to the limit of toleration. From time to time, to be sure, warnings have been sounded against the danger of overfeeding, but they have been less heeded than would have been the case if they had originated from convincing scientific experimentation, rather than from individual judgment, however good, based upon mere observation of gross phenomena.

To determine with any certainty the standard food requirements for tuberculous invalids, we shall have to make a more thorough study of metabolism than has yet, so far as I am aware, been done. It is not sufficient, as I have indicated, to compare the total nitrogen output of the urine with the total proteids of the food, but the feces must be analyzed at the same time in order to differentiate between endogenous and exogenous metabolism, and thus determine the amount of nitrogen required in the food to balance the pathological tissue catabolism. This means the clinical application on a large scale of the methods which have characterized some of the recent brilliant researches in physiological chemistry, and involves work practicable only in tuberculosis hospitals and sanatoria. A more careful inquiry into the whole subject, however, is assured when its importance is realized, for it must be conceded that it is not consistent practice to unnecessarily overburden the organs of digestion and elimination, and at the same time to insist upon body rest. By all means let us determine the food requirements, and meet them, if possible, but by acquiring more accurate data on the subject avoid the dangerous error of overfeeding.

MANIFESTATIONS OF SYPHILIS ASSOCIATED WITH PULMONARY TUBERCULOSIS.*

By JOHN H. PRYOR, M.D.,

BUFFALO, N. Y.

While some textbooks devote attention to the methods employed in distinguishing between the lesions of syphilis and tuberculosis, the recognition of the coexistence of the two affections has not received the consideration which it seems to deserve.

During the last two years I have observed fifteen cases of syphilitic disease associated with pulmonary tuberculosis. The diagnosis of tuberculosis was verified by the finding of bacilli in all the cases cited. In every instance a complete history of syphilis was obtained. All the patients had the initial lesion, marked secondary manifestations, and had undergone treatment. At the time of observation the in-

*Read before the National Association for the Study and Prevention of Tuberculosis, at its Second Annual Meeting, held in Washington, D. C., May 16-18, 1906.

terval which had elapsed since the appearance of secondary symptoms varied from one to fifteen years.

The cases are divided into two groups for clinical purposes. Eight exhibited syphilitic lesions and seven showed symptomatic manifestations, which promptly responded to the therapeutic test. The distinct, specific lesions found in seven patients were infiltration and ulceration of the larynx, pharynx, soft palate, nasal cavity, and tongue. Without exception these lesions had been regarded as tuberculous and the treatment was based upon that belief. In one instance a gumma of the neck had been followed by deep ulceration, which had existed for three weeks. It had been pronounced a carbuncle, and later ascribed to tuberculosis. In this series of cases proper local and constitutional treatment was followed by prompt relief and recovery. The mistake in diagnosis was apparently due to the fact that tuberculosis was held accountable because that disease was known to be present. Of the patients suffering from symptomatic manifestations, one complained of persistent frontal headache and myalgia, involving the muscles of the shoulders; one insisted that he had attacks of aphasia, vertigo, and numbness of a portion of the left arm: one suffered from neuralgia of the legs, particularly at night; sometimes the pain was confined to the heels alone, and four under the most favorable conditions showed no gain, or only slight increase in weight; anemia, languor, fitful appetite, and a daily rise of temperature to 100° or 101° for weeks. Suspicion of the latter group was aroused, because they were all incipient and favorable cases of tuberculosis. Complete rest, open-air treatment, and increased alimentation for a period varying from three to six weeks was not accompanied by improvement, or the symptoms grew more pronounced. When closely questioned, the history of syphilis was elicited and antisyphilitic treatment was followed by remarkable improvement.

Allow me at this time to anticipate the natural comment that any of these symptoms, and especially the diurnal rise in temperature, could have been caused by tuberculosis or mixed infection. Of the fifteen cases presented as suffering from the double infection of syphilis and tuberculosis twelve were regarded as incipient and favorable and three were moderately advanced.

We do not expect patients with a slight tuberculous lesion and little evidence of constitutional derangement to maintain a daily rise of temperature to 100° or 102° for weeks under modern methods of control. It is admitted that this may occur, but the fact that such behavior is unusual should incite a search for another cause, and syphilis should be suspected, particularly if gastrointestinal disturbance is absent.

Twelve of the fifteen cases were characterized by an evening elevation of temperature above 100°, and in three cases the temperature showed a persistent rise over that of the preceding day. I regard this manifestation in the class of patients under consideration as one of important diagnostic value. The effect of treatment upon the fever was most marked. In two instances the temperature dropped to normal in four days, and in the remainder it fell to normal, or 99°, in eight days.

At the present time we are still compelled to accept the therapeutic test as evidence in the detection of syphilis and its multiform phases. It is doubtful if the dual infection or association of the two diseases renders a prognosis as unfavorable as the literature might lead one to presume. Eight of the patients apparently recovered from tuberculosis, and in seven the disease was arrested. Of course sufficient time has not elapsed to pass judgment upon the ultimate result.

The difficulties in the administration of the iodides to the syphilitic and tuberculous patient have been exaggerated. This is particularly true of persons afflicted with incipient tuberculosis. Iodide of potassium was given in solution, or with the essence of pepsin, in doses ranging from five grains to fifty grains three times daily, and was not followed by any more disturbance than that usually encountered when syphilis exists alone. Careful attention was paid to the behavior of the tuberculous focus in the lung with reference to the influence of iodide of potassium upon the diseased process. In one instance the moist râles and the amount of expectoration were increased, but in all others no change of this character was detected.

Mention should be made of one case characterized by the interesting clinical phenomena which have sometimes proved puzzling.

B. F., aged forty-five, had secondary manifestations twelve years ago; no symptoms since. Four months before coming under observation was treated for pleurisy at base of left lung. Three months ago he began to lose weight, developed some evening temperature, and a cough with expectoration. One month ago bacilli were found, and a diagnosis made of pulmonary tuberculosis. Upon examination I found evidence of a lesion at the left apex, and also one at the base of the left lung. Both were active, and the one at the base seemed to be undergoing softening. Bronchial breathing and an abundance of fine, moist râles were present. After three weeks had elapsed I noted that his general condition was improved, but the temperature gradually rose in spite of absolute rest. Suddenly he developed nervous symptoms, which seemed distinctly syphilitic in origin. A full history of syphilitic infection was admitted. During my absence for a period of two weeks his symptoms became more pronounced and he was given thirty-five grains of iodide of potassium three times a day with daily inunctions of mercury. After three weeks of this treatment I found that all pathological physical signs had disappeared from the base of the lung, with the exception of slight relative dullness, and the improvement in the signs at the apex was quite remarkable. The great change in the physical condition and signs and the decline of the temperature to normal led an able clinician, who had observed the patient during my absence, to the conclusion that the thoracic disease was entirely due to syphilis, and the diagnosis of associated tuberculosis was regarded as erroneous. Three weeks later I examined the patient again and found no evidence of disease at the base, but the signs of a quiescent or arrested lesion at the apex. The temperature continued normal. It seems fair to assume that he was suffering from a dual infection of the lung, and it seems probable that the disease at the base of the left lung was syphilitic and that at the apex tuberculous.

Some years ago I observed two advanced cases in hospital practice of the type earlier described as syphilitic phthisis. They were cases of tuberculosis with syphilitic taint, and possibly a closer study will sometimes explain the rôle played by obscure manifestations of syphilitic poison in changing the clinical picture exhibited as due to hopeless tuberculosis.

The purpose of this brief and general presentation

of a few cases is to attract attention to the following conclusions:

Pulmonary tuberculosis is often held responsible for too many manifestations of disease which are due to other causes.

The fact that a patient has tuberculosis should not be an excuse for disregarding these conditions, which often have a decided influence upon the prognosis and cause much avoidable discomfort.

Syphilis is a common disease, and physical debility combined with worry and mental distress, which may accompany tuberculosis, may arouse a latent syphilitic taint.

The association of the two morbid conditions may be disguised and the symptoms confused.

Furthermore, many of the manifestations of syphilis are quite similar to those produced by tuberculosis.

The diagnosis of syphilis, in connection with tuberculosis, will require close scrutiny, and often the therapeutic test.

Persistent fever above 99.5° in incipient cases of tuberculosis, when the lesion is slight and the general condition not much impaired, and when rest with proper treatment for a period of three or more weeks fails to secure an amelioration, should be viewed with suspicion and the possibility of associated syphilis thoughtfully considered. This is also true when atypical pneumonia or intractable subacute bronchitis supervenes.

It is questionable at least if the prognosis in tuberculosis of the lung of an incipient type is rendered any more unfavorable when syphilis, particularly of the tertiary form, is also actively present.

The improvement in the tuberculous case following antisyphilitic treatment is most marked, and at times surprising. This is particularly noticeable in reference to the prompt and decided drop in temperature.

Unless my experience has been very unusual, syphilis is more often associated with pulmonary tuberculosis than the paucity of the literature upon the subject would indicate.

The concurrence of the two diseases must be more common in hospital, dispensary, and sanatorium practice than is assumed by most authorities.

In this paper no allusion is made to the differentiation between the two affections. The simple intent is to emphasize the importance of recognizing their coexistence and the efficacy of proper treatment.

26 Linwood Avenue.

REFLEX SYMPTOMS AND REFERRED PAINS CAUSED BY STONE IN THE KIDNEY.*

By STELLA STEVENS BRADFORD, M.D.,

MONTCLAIR, N. J.

The claims to attention of the case which forms the theme of the present paper are based upon its having been for two years under the observation of physicians of eminence and experience before a diagnosis was agreed upon. That such uncertainty was inherent in the character of the case is apparent from the suggested diagnoses—neurasthenia, hysteria, neuritis, neuronitis, spinal cord involvement, tuberculous spondylitis, exophthalmic goiter, Addison's disease, appendicitis, oophoritis, retroversion, nephroptosis, chronic arsenic poisoning, and flat-foot. The patient, a woman far above the average in education and intelligence, realized her own limitations as diagnostician and therapeutist, and faithfully carried out the instructions of the general practitioner or specialist under whose care she had placed herself, dreading nothing but invalidism, and willing to do anything which would give her health and the ability to work. The rest cure was advised, and she remained in bed five months. Walking and the use of will power were enjoined; she walked till, in the old phrase, she could no more. She resorted to plates in her shoes, electricity, travel, and time—all under direction, and all to no avail.

She came to me in June, 1905, with an introduction from Dr. Charles L. Dana, asking me to take charge of her and see if I could find any evidences of organic trouble, and stating that she had had glycosuria, and when he saw her a tachycardia, possibly inconstant. He also said that she might have had a neuritis or neuronitis, according to the report of an eminent Chicago neurologist, whom she had consulted previously.

To quote this report: "I saw Miss ———, April 1, 1904. The history was very confusing, embracing a number of symptoms which apparently were purely functional, and also showing evidence of some sort of gastrointestinal disturbance which must have been rather severe. On the strength of the pain and weakness in the legs, noninvolvement of the sphincters, and weakness of the knee jerks, with abundant sugar in the urine, I concluded that the case was probably one of neuritis with a considerable hysterical element added. When I saw her the Achilles jerks were pretty good, but the knee jerks could be elicited only by reinforcement. The gait was rather characteristic of hysteria than of organic disease, and with some encouragement and some suggestive treatment she was able to trot up and down my office, holding to my hand—a thing that seemed absolutely impossible when she first came into the room."

It was according to this neurologist's suggestion that she exerted her will power to the utmost, walking as far as she could, then resting, and walking again. It was always with pain and conscious effort, and the length of walk possible was always limited by increasing stiffness and weakness.

Change, travel, rest, and escape from doctors were advised, so she came East and spent the winter living as normal a life as possible. Since no improvement resulted, she appealed to Dr. Dana, and his opinion was as already given. Acting under his advice, the following exhaustive history was taken and examination made, in the search for a possible organic cause:

The patient was born in the United States; age, thirty-two years; occupation, that of librarian. The chief complaint was of pain and weakness of the lower extremities. The family history was negative; mother is nervous and easily worried; father, brothers, and sisters are living and well.

Past History.—She was well as a child, except for "malaria," which was common in the city where she lived. She taught from the age of nineteen to that of twenty-one, when she was obliged to stop because of pain in her back, lumbar region, which was increased by standing. She suffered at that time also from insomnia. Eight years ago she had an attack of "appendicitis" or "oophoritis," duration, six weeks, with severe localized pain and high fever. She has been conscious of a tender spot in her right side ever since. Menses began at sixteen; regular; duration, two to five

*Read before the Cornell Medical Alumni Society, February 23, 1906.

days; flow moderate, never profuse; accompanied by pain, which was never severe; is worse now than formerly, extending from the back around through the iliac and hypogastric regions, and is usually worse on the right side. Her nervous symptoms are worse during period. Leucorrheal discharge is infrequent and hardly appreciable.

Present History.—For three years she worked very hard as librarian, studying for examination at the same time, and paying no attention to sleep or exercise. Feeling "run down," she took arsenic and strychnine for a long time. She felt weak and noticed that her legs trembled, but did not stop work till forced to do so by an attack of diarrhea, which was painless, but lasted several weeks and completely exhausted her strength. This was followed by pain, or a "clutching sensation," beginning in the back and radiating at first down the anterior aspect of the thighs. The pain later involved the whole of the lower extremities, especially the knees, which were held flexed. It was bilateral, but the patient always regarded the left leg as the worse. The weakness in both lower extremities was extreme, but the power of motion was never wholly lost. The patient remained in bed five months because of this pain and weakness, receiving some electrical treatment. For about two years, *i. e.* from the time she stopped work till I first saw her in June, 1905, there had been very little improvement. The pain was still almost constant, involving back, lumbar region, thighs, legs, and ankles. It was superficial and burning, or deep, dull, and aching in character, and was sometimes accompanied by sharp, stabbing sensations. It was often associated with a feeling of cold. It was worse after walking, when it was accompanied by stiffness and weakness; it often interfered with sleep, but was relieved by the recumbent position.

Other symptoms were frequent urination, especially at night, not accompanied by pain or burning; pain in the back of the neck, and extreme exhaustion after any effort, as in reading or sewing, or after talking with several people. She spoke often of "waves of weakness" which passed over her. Her appetite was fair. She had no indigestion, and her bowels were regular, the stools, however, sometimes ribbonlike.

Her mental condition was excellent, and her memory good, but she was inclined to be apprehensive, especially at night and in crowds, and to be discouraged about her condition. Her sleep was fair, but broken by pain.

Physical Examination.—Complexion, dark, and said to be growing darker. Pale, with dark circles under eyes. Expression anxious, worn, hunted. Well nourished, flesh firm. Slightly enlarged thyroid, no exophthalmos. Tongue normal. Heart: slightly accentuated second aortic sound, otherwise normal. Pulse, medium in force and tension, slightly irregular in rhythm, varying in rate from 96 to 108. There was no thickening of the arteries. Lungs: Negative, except for roughened breathing and increased voice sounds at apices. Spine: Marked prominence of first two lumbar vertebræ; no tenderness on pressure of any kind, no rigidity, no disturbances of sensation on back. Lower extremities: White, especially the feet, with tendency to cyanotic mottling; always cold, though the examinations were made in June and July. No pulsation was obtained in dorsalis pedis, nor posterior tibial artery of either side, though examinations were many times repeated, except once, and that once was after a two days' rest in bed. Then the pulsation, though obtainable, was weak. No atrophy. Abdomen: No rigidity. Liver normal in size. Both kidneys palpable, the right movable; neither tender. Tenderness, not constant, in region of appendix, on deep pressure. Pelvic examination: Prepuce free from clitoris; transverse contractions in labia minora. No discharge. Cervix in normal horizontal plane, hard, directed somewhat anteriorly. Uterus small, not infantile, retroverted, and sharply retroflexed. Ovaries large, tender, especially the right, and prolapsed. Uterus movable, but not completely replaceable.

Roentgenograph showing renal calculus

Neurological Examination.—Cranial nerves negative. Patellar reflexes obtained, variable, the left usually the stronger; reinforcement usually but not always necessary. Achilles and plantar reflexes normal and equal. No loss of motor power. No disturbances of sensation. No ataxia. No disturbance of deep sensibility. No romberg. Gait unsteady, weak. Urine: Twenty-four-hour amount, 50 to 70 ounces; pale amber, cloudy, abundant flocculent sediment, faintly acid, specific gravity 1010 to 1016, trace of albumin, no sugar. Microscopical examination: Very numerous pus

cells, few epithelial cells, chiefly caudate. Repeated examinations gave the same results, and a catheterized specimen confirmed them. No tubercle bacilli found. I have not succeeded in getting the report of former urine examinations from the physician, but the patient's own statement, accurate in other respects, was to the effect that there had been sugar, and also pus which was attributed to vaginal discharge. Blood: Hemoglobin, 80 per cent.; red blood cells, 4,368,000; white blood cells, 9,000; polynuclears, 65 per cent.; small mononuclears, 29 per cent.; large mononuclears, 5 per cent.; eosinophiles, 5 per cent.

The salient points, then, in the symptoms were nervous exhaustion, and pain and weakness of the lower extremities; and in the examination, moveable right kidney, pyuria, retroversion of uterus, and defective circulation of the lower extremities.

The syndrome of pain and weakness in the legs, comparatively absent during rest, especially in the recumbent position, much increased by walking, and going on almost to rigidity and loss of power, with absence of pulsation in the dorsalis pedis and posterior tibial arteries, was very suggestive of the intermittent claudication so ably described by Dr. J. R. Hunt in the MEDICAL RECORD for May 27, 1905. According to this author, "It is generally admitted that the symptoms are ischemic in origin, the manifestation of a temporary anemia of the muscles, nerve endings, and other structures." And again, "Three factors must be recognized in the production of the claudication ischemia: one, constant and organic in nature, diminishing the caliber of the vessel, and two factors, inconstant and functional, the tendency to vasomotor spasm and the increased demand upon the circulation of the part during activity." He also says, however, that "some observers * * * suggest a purely functional form of the disease, or one in which the structural alterations of the vessels play an entirely subordinate rôle."

In the case in question there was no evidence of arteriosclerosis or endarteritis, "diminishing the caliber of the vessel"; hence, if the syndrome above mentioned constitute intermittent claudication, this case must be considered one in which the symptoms were caused either by pressure plus vascular irritability, or the cause must be wholly reflex.

According to the abdominal and pelvic examination given above, as confirmed by Dr. William M. Polk, who was called in consultation, there seemed to be no possibility of pressure which could interfere directly with the blood or nerve supply of the lower extremities. It was Dr. Polk's opinion, also, that the retroversion of the uterus was a possible, but not a probably adequate cause of the symptoms. There remained the pyuria, which he considered might be due to a pyelitis caused by torsion of the pedicle of the movable right kidney. Nephropexy was tentatively advised, provided that ureteral catheterization, which he recommended, shed no new light.

Cystoscopy and ureteral catheterization were performed by Dr. F. Tilden Brown. The result was dramatic in the extreme, for, though the movable kidney, the appendical or oophoritic pain, and the tender ovary were all on the right side, from the right ureter clear amber urine flowed freely, while from the left flowed slowly, a thick, whitish fluid. Dr. Brown's report was as follows:

SPECIMEN FROM	RIGHT URETER.	BLADDER.	LEFT URETER.
Amount	18 c.c.	5ii.	7 c.c.
Appearance	Clear.	Cloudy when drawn; clear, supernatant fluid after standing.	Turbid.
Color	Amber.	Amber.	Pale, watery.
Sediment	Just visible.	Heavy, white, small amount.	Marked, heavy, white.
Odor	Normal.	Aromatic.	None perceptible.
Sp. Gr.	1005.	1015.	1004.
Reaction	Acid.	Acid.	Faintly acid.
Albumen	Negative.	Per Esbach, 1-5 gm. per L.	Marked reaction (pus).
Sugar		Negative.	
Urea	0.6 per cent.	1.3 per cent.	0.4 per cent.
Indican		Negative.	
Blood		None found.	
Pus		Bulk of sediment.	Bulk of sediment.
Mucus		Small amount.	
Epithelium	Sediment made up of few squamous, round and oval cells, as from the ureteral mucous membrane.	Few squamous and round, as from bladder mucous membrane.	Few round, oval and caudate, as from ureter or pelvis mucous membrane.
Casts		None found.	
Bacteria	None found.	Few bacilli.	Few bacilli.
Crystals and amorphous material	Negative.	No tubercle bacilli found. Small amount of amorphous matter.	No tubercle bacilli found. Negative.

To quote his conclusions: "I am impressed with the likelihood of a left-sided renal tuberculosis, involving perhaps the corresponding adrenal. The state of the bodies of the vertebræ, the left kidney, and the adrenal constitute a focus from which all the symptoms could reasonably be deduced."

Three possibilities, then, carcinoma, tuberculosis, and stone, were under consideration. Absence of red blood-cells in the urine argued against all three; absence of cachexia against carcinoma; absence of emaciation and afternoon temperature—it was repeatedly tested—against tuberculosis; absence of renal colic against stone. Carcinoma was considered by far the least probable.

Culture tests were made by the recognized expert, Dr. Emanuel Libman, of Mount Sinai Hospital. The result showed that the urine from the right side was sterile, and from the left side, contained only *Bacillus proteus vulgaris*. Though this greatly reduced the chances of tuberculosis, the guinea-pig test was under consideration, when, at Dr. Brown's suggestion, an *x*-ray picture was taken by Dr. Alfred T. Osgood. The result very clearly confirmed the diagnosis of stone, as is shown by the accompanying picture (page 96).

Operation was of course in order, but, for family reasons, the patient went to Cleveland to have

it performed. I quote the report of the operator, Dr. James C. Wood:

"On Thursday, September 7, I operated. I felt convinced that the sharp retroflexion of the uterus and the appendix were responsible for no little trouble. I therefore first opened the abdomen and fastened a small, almost infantile uterus in front by ventral fixation, the round ligaments being so small and atrophied that I felt it would not do to rely upon them to hold the organ in place. The appendix was hard, indurated, and intimately adherent to the cecum. I therefore removed the appendix in the usual way. The kidney was explored and the stone readily felt within its pelvis. The kidney was, however, a mere sac, the pancreas being closely adherent to it, so that it was with difficulty that the pancreas was separated from it. After the abdomen was closed the kidney was exposed through the usual posterior incision. The spleen was enlarged and crowding hard down against the kidney. The kidney was closely adherent to the surrounding structures, there having been evidently some time a severe perinephric inflammation.

"To make a long story short, I had to injure the pancreas somewhat in getting the kidney out, and the shock was too much. She died on the third day, with a temperature which during the first twenty-four hours was subnormal and which was but slightly above the normal at the time of her death. A post-mortem showed beginning fat necrosis of the omentum as a result of the injury to the pancreas. The question naturally arises as to whether or not pancreatic implication was not responsible for the presence of sugar in the urine before she came to me and to you."

In answer to further question, he says: "I do not think there were any adhesions posteriorly that would interfere directly with the blood or nerve supply of the extremities."

The stone, which he forwarded me, was brownish-gray, irregular in shape, but with no sharp points, about ¾ x ⅜ of an inch in its greatest diameters, and resembling volcanic tufa in surface and consistency.

The last word is, however, not yet said, for many questions remain unanswered, in spite of the termination in autopsy. For instance, there was at one time glycosuria, which was said to be functional. Was it functional? Is it ever functional? Does it ever exist as a result of pressure on the pancreas by neighboring organs, or as a result of surrounding inflammation, or as a direct reflex from the pathological condition of another organ, as the kidney?

Moreover, there is a confusion hard to clarify resulting from a certain looseness in the use of some medical terms, as "reflex symptoms." Attempting to define: Reflex symptoms are those manifestations of the functions of the body, mind, or spirit, evidenced as pain, discomfort, stupidity, or irritability, which might be the result of bad heredity, absence of hygiene, or financial disability, but which, when they exist simultaneously with a physical arrangement considered by anatomists or physiologists pathological, are attributed to it. For example, in this case the uterus was retroverted. Therefore "waves of weakness," apprehension in crowds, and pain and weakness of the legs had been indiscriminately attributed to it, with regard neither to the nerves supplying the parts concerned, nor to the fact that many a retroverted uterus gives no symptoms. Since in the present case the general reflex symptoms, which have been above defined, have so many entirely adequate causes, including two years of pain, physical examinations, and enforced idleness, we will consider here merely the actual pain and weakness.

Following Henry Head, the great English authority, in his work on the definite cutaneous areas of pain and tenderness due to visceral disease, we may fairly regard the pain experienced in the case under consideration as "referred." A brief anatomical review is essential to its understanding.

Keeping in mind that the nerve supply of the kidney is from the renal plexus, *i. e.* indirectly from the solar and aortic plexuses and lesser and least splanchnic nerves, and that the nerve supply of the pancreas is derived from the solar plexus, and that these plexuses are in communication with the lumbar spinal nerves, and, by way of the splanchnics, with the tenth, eleventh, and twelfth dorsal spinal nerves, it is natural to expect that the segments of the spinal cord involved would be the tenth, eleventh, and twelfth dorsal, and the lumbar.

Henry Head has mapped out the respective areas of cutaneous hyperalgesia due to different visceral diseases according to the findings in acute cases of known diagnosis. Referring to his work, I find that the segmental areas ascribed to the kidney are the tenth, eleventh, and twelfth dorsal and the first lumbar. He, however, has found no case of visceral disease giving cutaneous hyperalgesia in the second, third, and fourth lumbar segmented areas.

During my examination of the case in question there was no cutaneous hyperalgesia, a fact easily explained by there being no acute disease. On the other hand, the superficial pain was referred with fair accuracy to the area assigned by Dr. Head, namely, beginning in the back, lumbar region, it radiated downward and forward across the anterior and inner aspect of the thigh.

Considering the fact that the pain was deep as well as superficial, grinding as well as burning, involving at times the muscles of thighs and calves, and the knee and ankle joints, I would suggest the following double explanation:

1. The irritation in the kidney or pancreas or both caused the so-called referred pain of Head—many years ago described by Dana under the term "transferred pain"—the pain being superficial, burning, and limited to the back, abdomen, and upper thighs.

2. The irritation in the kidney or pancreas or both brought about reflexly a spasm of the vasomotor nerves, derived from the lumbar and upper sacral segments, causing contraction of the blood-vessels of the lower extremities. The resulting ischemia in the nerve endings was the cause of the deep-seated pain; and in the muscles the cause of the weakness.

The possibility that an ischemia, due to direct pressure on the large blood-vessels, had caused indirect nerve changes was ruled out because there was no such pressure. Whether there was at any time an actual neuritis, it is impossible to determine.

In conclusion, I would express my hearty thanks to the eminent men consulted, for the unusual interest taken, and for their scholarly patience in following the small clue which led at last to a correct diagnosis, although, unfortunately, not to a cure.

THE OPHTHALMOSCOPE AS AN AID TO THE GENERAL PRACTITIONER.*

By CLARENCE P. FRANKLIN, M.D.,

PHILADELPHIA, PA.

When Dr. Darnall asked me to write a paper for you, I felt like saying, in the words of Cicero: "You have often urged me to write something on this topic, and it appears to me also to be one that is worthy of the consideration of all, and especially of such friends as ourselves."

This is not a technical discourse on refraction or eye diseases, a mass of dry figures and stated cases, of "wise saws and modern instances," but a simple plea for a strengthening of your own resources, a plea arising from a deep-seated wish to see the general practitioner assert more fully his rights to enter, if only on its borders, the field of the eye specialist, to the end that there may be a closer union between what I may call the Generalist and the Specialist.

For I speak from experience when I say that ten years of general practice, before I devoted myself wholly to a specialty, taught me the value of a knowledge, however superficial of the specialties.

Not that a man should be "Jack of all trades," for that produces its natural concomitant, that he is "master of none," but that his character as a physician may be rounded out and filled to its perfect form. The specialist who has never engaged in general practice is a one-sided man; he is like a painting, he may have height and breadth, but no depth—he lacks, in other words, the third dimension, which is supplied to the physician only when he studies disease in all of its possible manifestations.

Or, to use another figure, if we accept William Cullen Bryant's dictum, when, in his magnificent "Thanatopsis," he says: "To him who, in his love of Nature holds communion with her visible forms, she speaks a various language," then is it true that while the general practitioner who is versed in the specialties is able to translate all these various tongues of our Old Mother, the specialist, "each in his narrow cell forever laid," can read but one dialect.

I can realize the peculiar position held by you in this great city for seekers after health, and can understand how it is that you must practise the specialties here yourselves, else would your patients seek "fresh fields and pastures new;" and so, I plead for an advance upon your part in the direction of my chosen field of work.

I am suggesting that you perfect yourselves in the diagnosis, at least, if not the treatment, of eye conditions, which are considered by the general practitioner in my city, as being beyond his ken, but which to you, famed as you are as successful healers of the sick, forced by your environment to become more catholic than those of us of the larger cities, can easily become matters of mere routine. Therefore, the most practical suggestion, if I may be permitted, is that you familiarize yourselves with the use of the ophthalmoscope in your general practice.

Ill would it become me to speak ex-cathedra to such a learned body of men as have honored me with their attention to-night, even if the time permitted, but a mere bald statement of some of your daily cases will show you how this little instrument can be of the greatest service to you. No weighty apparatus is needed, no dark room is used where the modern electrical instrument is at hand, and rarely, for your purposes, is a mydriatic required.

*Read before the Atlantic City Academy of Medicine, March 9, 1906.

Instead, your stethoscope is paired with your ophthalmoscope, and your kidney and heart cases, your brain lesions, your eyestrain headaches, and general refractive errors are diagnosed and brought forth from obscurity by this instrument. So that the systematic use of the ophthalmoscope in the investigation of general disease is, I feel, of sufficient importance to warrant my bringing it to your attention in this way this evening.

The eye-man is not always called in for his opinion in rare and unique cases, alone, but in every-day, common cases of complicated disease in ordinary general practice, and this, while it may be good business for the specialist, makes in the long run, for a stunting of the mental growth of the general practitioner, as the latter might just as well make his own diagnosis unaided in a large class of cases which he now calls upon the ophthalmologist to clear up for him.

Most recently I was asked to discuss a case reported at a meeting of an obstetrical society; a case of blindness occurring during eclampsia (in which case I had been previously called in consultation) in a pregnant patient, where the use of the ophthalmoscope by the family physician would have shown, by the total lack of any retinal pathological conditions, that the blindness was not due to any eye disease, but merely an eye-symptom of a general condition, and one which would, and did, clear up of itself, as the general state was bettered.

This is only one case out of many in which the eye-man sees that the general practitioner can just as easily form his own judgment without other aid than that afforded by the ophthalmoscope. Of course this implies that a man has ability sufficient to distinguish between eye-symptoms arising from ocular conditions, and eye-symptoms arising from general states, such as some of the pathological conditions of the kidneys, stomach, nervous system, etc. On the other hand, the general practitioner can, by a wise use of the ophthalmoscope, detect not only many general conditions, but also many ocular abnormalities in their incipiency, and by turning them over to the eye-man temporarily for treatment, save much loss of peace, time, and money to such patients.

The ophthalmoscope has its use, or it would not have been produced by the brain of man; this is just as much a result of natural laws as is the presence of light, air, water, or any other natural phenomenon. There is a cause for each, and our part is, as thinking beings, to investigate each, in order to make the best use of it. This is far better expressed by the wise old slave Epictetus, who said: "If God had made colors, and not made the faculty of seeing them, what would have been the use? None! On the other hand, if he had made the faculty of vision, without objects to be seen, what would have been the use of that? None, again! If he had formed both the faculty and the objects, but had not made light? Neither in that case would they have been of any use. What, then, is to be done? To make the best use of what is in our power, and take the rest as it happens."

The cause for the invention and production of such instruments of precision as the ophthalmoscope is no doubt due to a naturally existing skepticism in the human mind, of which Huxley speaks when he says: "The improver of knowledge absolutely refuses to acknowledge authority, as such. For him, skepticism is the highest of duties, blind faith the unpardonable sin." So, it is because we want to see what is inside the eyeball, and not guess at it, that we turn to the ophthalmoscope in many conditions.

Should you, in familiarizing yourselves with this

instrument, wish to know more about refractive conditions, so that you may recognize them, at least, read such a book as Morton's little work on refraction; and if you would know more about eye-symptoms in general, read Nettleship's "Diseases of the Eye," although both of these Englishmen, like all European ophthalmologists, ignore conditions which, minor to the uninstructed eye, have most important bearings on the general welfare of the patient. It seems to be a fact that, among the general run of European patients, even of the better classes, lesser degrees of eye troubles are ignored, as for instance any refractive error of less than half a diopter of hyperopia, myopia, or astigmatism is neglected, as witness the general use of the monocle in the United Kingdom—a practice which is a relic of barbarism, and which should be relegated to the back attic of oblivion, along with the warming pan and the candle snuffers.

I often find English students arriving in this country complaining of typical eyestrain symptoms, wearing corrections not entirely covering their cases, and seeming to prove the statement just made. Is this due to the more phlegmatic life abroad failing to make the correction of these minor ills of paramount importance? It would seem to be more this—the mode of life—the lack of strenuosity, than due to racial characteristics, for the same students who will tell me that they never had any further eye difficulty while living abroad after putting on the correction ordered by some well-known foreign ophthalmologist, will go on to say how they have, since entering upon the pursuit of a profession in this country, become conscious of defects of eyesight of which they were hitherto ignorant. Verily, the strenuous life becomes not only the simple one, but the foolish one, when it produces such effects as these.

Many times have I seen the most marked effects produced by the addition of a one-eighth diopter to a lens, either spherical or cylindrical, and this being so, who is at fault? Anyone? Is it the patient who is wrong, or the prescriber? Are our practitioners better taught in the minutiæ of eye practice, or do we teach our patients too much introspection, and give too much suggestion by our close questioning after fine details, so that the patient notices things which he might hitherto have been ignoring, to his own comfort and welfare? Be that as it may, often have I seen all the difference between comfort and distress produced by the addition to a correction of so little as a one-eighth diopter, or the alteration by so little as five degrees, in the axis of a cylinder.

But to speak more specifically of a few of the conditions which, in the practice of the family physician, call for the use of the ophthalmoscope as a diagnostic instrument.

Any interference with the circulation causes eye changes which can be readily observed, for diminished blood supply leads to insufficient nutrition, and consequent danger to the optic nerves, while, on the other hand, increased blood supply shows itself to the ophthalmoscope as overfilled retinal vessels. The changes in the intima of the capillaries throughout the system are more readily recognized, perhaps, in the eye, by means of the ophthalmoscope than elsewhere, so that the conditions which have an intimate relation with the circulation, in which the ophthalmoscope is of use, are arteriosclerosis, atheroma, syphilitic changes, leukemia, and chronic poisons. The pulsations of the retinal arteries in aortic insufficiency are readily seen, of course, especially when synchronous with the pulse and alternating with filling of the veins. This condition, due to a compensating hypertrophy of the left ventricle, may affect even the most distant capillaries.

An infective embolus, as from purulent affections of the lungs or uterus, etc., or an ulcerative endocarditis, may cause panopthalmitis, or destructive choroiditis, but of course the noninfectious emboli are much more common, and it depends upon whether the choroidal or retinal vessels are plugged to say how much damage can be done, as in the former case less mischief occurs, owing to the intimate choroidal anastomosis, and hence less blindness is found than in the case of the plugging of a retinal vessel, where the vessels are a part of a terminal circulation, so that such a thrombosis causes functional blindness in the whole area supplied by the occluded vessel. These changes and the embolus itself are often brought to view by the ophthalmoscope, thus much helping the general practitioner in his grasp of the cases of partial blindness which occur among his patients with vascular changes.

While "choked disk," so-called, is found in many other conditions, such as in cerebral hemorrhage, anemia, brain abscess, diabetes, and albuminuria, it proves itself to be caused in about 70 per cent. of all cases where it occurs by some form of brain tumor. Usually bilateral, when the ophthalmoscope shows it to be one-sided the neoplasm is to be located in the corresponding anterior lobe of the brain.

Meningitis and multiple sclerosis are among the nervous affections that give occasion for the use of the ophthalmoscope, while the peculiar gray disk of the optic atrophy of locomotor ataxia is well worthy of study as one of the characteristic symptoms of this terrible disease.

While only about 10 per cent. of all the various diseases of the kidneys are associated with ocular changes, still the retinal and optic nerve lesions, when present, are characteristic, and often the kidney lesion is detected in advance of the general symptoms.

When we realize that a conservative estimate places 40 per cent. of all headaches to the credit of eyestrain, and 80 per cent. of all frontal headaches, we can realize how important it is to make accurate diagnoses of existing ocular anomalies.

In such cases as I have just hastily sketched, to say that the ophthalmoscope is the mainstay of the diagnosing physician is merely to give expression to a trite phrase, for the value of this instrument has long been proved.

That abnormalities of the eye are in far greater proportion than normal conditions is well shown by Metchnikoff, when he says: "The eye, one of the means by which we are conscious of the outside world, presents a natural disharmony"; and he then goes on to quote Helmoltz as saying: "'Nature seems to have packed this organ with mistakes, as if with the avowed purpose of destroying any possible foundation for the theory that organs are adapted to their environment.'"

Far be it from me to say that all eyes are abnormal, or that every patient who appears complaining of apparent eyestrain needs glasses, for while an absolutely perfect or emmetropic eye is as hard to find as would be a perfectly arched roof to a mouth in which to fit an ideal dental plate, nevertheless the true rôle of the ophthalmologist is not only to relieve or cure abnormalities, but also to detect readily the first point at which to stop and say: "Thus far and no further; this case is for the general practitioner to treat, these eye-symptoms are only originated by pathological conditions in some other part of the body, such as the teeth, the stomach, the nervous system, etc."

And then does the Simon Pure ophthalmologist do what his enemies claim he never does—return the patient without glasses, to have his distress re-

lieved by removal of the distant cause of trouble.

To accomplish this end, which, after all, is the true end and aim of our profession in general—the relief of human suffering—the general practitioner can do much by familiarizing himself with the ophthalmoscope and its uses as a diagnostic instrument.

The practice of medicine has now so far advanced that a knowledge of the use of this little bit of apparatus and a proper understanding of the things it reveals to the observer's eye are absolutely necessary in the equipment of the modern general practitioner in his never-ending war against pain, disease, and death.

How much suffering from uncertainty, and how much complication of worldly affairs, could be obviated if the general practitioner were able, for instance, to tell his patient how long he had to live, within a few months, or a year or two at the most, after observing the typical changes in the retina in Bright's disease in many cases? How easily relieve the anxiety of the relatives, already wrought up to the breaking point by the ordinary worry and strain of labor on the part of the mother, suffering from eclampsia, if he can readily and absolutely assure them that the terrible blindness in the mother, shutting down like a pall of death at a time when the full possession of all the faculties is such a priceless boon, will promptly disappear within a stated time? How soon relieve the heartache of the loving mother, who sees her newborn child with crooked eyes, and a future, to her imagination, of handicap from defective ability, by telling her that, since the ophthalmoscope shows no organic lesion in the sight apparatus, there is a reasonable certainty that her offspring's eyes may be, and will be, straightened again, as nature intended?

Can the aged, with incipient cataract, advancing with all its deadly chill of nightlike blindness, find comfort in the words of cheer of their family doctor? Yes, when he has, through the thin veil of oncoming opacity, seen, before it is too late, that retina and vitreous and nerve are normal, then can he predict sight again, and tell his trusting patient that after passing through the oncoming valley of the shadow (for such it may be truly called, this gradual withdrawal from the aged of their one choice possession left them by advancing years—their sight, and all the occupation and comfort it affords their declining days), after this descent into the depths, I say, new sight is to come to them, like a resurrection, and that again they may have that great privilege, a privilege seldom appreciated until its threatened withdrawal centers attention upon its blessedness—the grace to look again upon God's good green earth, and sky, and sunshine. How much more greatly may the bounds of usefulness be extended of him who, far more than priest or parson, is truly the "guide, mentor, and friend" of suffering humanity, the general practitioner?

If, as Pope says, "the proper study of mankind is man," how much more can we do for his spiritual side by first making ourselves as nearly as possible perfect in our knowledge of his physical being, granting, and willingly, that the spiritual is capable of full development only with a perfect physical condition as a foundation?

This digression into the metaphysical side of our duty to our fellow-man is called forth by the query often put by a certain type of general practitioner, when a proposition such as that presented to-night is placed before him: 'Why take the trouble to perfect myself in the use of this or that instrument, when my time is already more than filled with the use of the vast number of diagnostic aids which I must use to keep me abreast of the times; why burden me more? I do well enough."

But such a man looks not to the evercoming tomorrow, to him the wheels of Progress belong but to the Car of Juggernaut, to crush the prostrate forms of those who lie sluggish among the rattling bones of antiquity's precepts. Such a man cries, with Omar, the Tent Maker of Khorassan:

> "'Tis all a Checkerboard of Nights and Days
> Where Destiny with Men for Pieces plays
> Hither and thither moves, and mates and slays,
> And one by one back in the Closet lays."

But the old Persian Khayyam in his verses pictures the life of ease and flowers, of the winecup and song, the dallying of those of "Mrs. Warren's Profession," and the Rubaiyat can be epitomized in the modern cynical phrase of slang, "What's the use?"—which again is best answered by another writer of old, the noble old Roman Emperor, Marcus Aurelius, who, in his "Meditations," said: "The joy of man is in doing man's proper work," and this consists in zeal in the furtherance of Nature's chief aim, the production and maintenance of a healthy human race.

121 South Sixteenth Street.

Nerve Blocking to Prevent Amputation Shock; Illustrative Reports of Two Thigh Amputations.—Herman B. Gessner reports two cases of amputation in which he used nerve blocking with good results. The first patient was a colored man twenty-three years old. He suffered from tuberculosis of the right knee-joint and femur, with partial ankylosis. A long anterior and short posterior flap amputation was done at the middle of the thigh. When the posterior flap was being made, care was taken to identify the great sciatic nerve. This was edematized with 25 minims of a 2 per cent. solution of cocaine hydrochlorate, and then divided at the edematized level. After the amputation was finished, the great sciatic and the internal saphenous nerves were edematized with the same solution on being drawn out for shortening. Twenty-five and ten minims were used on them respectively. The character of the pulse was excellent throughout the operation. The writer then cites the history of another case in which cocaine was used to block the great sciatic before division, and the same nerve and the internal saphenous before shortening. In all, 75 minims of a 1 per cent. solution were used. No difference in the quality of the pulse was noticed as the result of the amputation. The writer recommends this method as one well worthy of further trial. Only a minute or two is required for the blocking.—*American Journal of Surgery.*

Strangulated Inguinal Hernia in an Infant of Two Months.—Edward Guion describes this case. All efforts at reducing the hernia were unsuccessful. The patient was so weak that general anesthesia was considered extremely dangerous and inadvisable. An incision over the inguinal protrusion was made. Great care was taken in separating the tissues until the sac was reached. This was opened and the strangulated part of the bowel was replaced. Although this part of the bowel was greatly discolored, its condition promised continued vitality. The opening was closed by through-and-through sutures, no attempt being made to dissect out the delicate structures. The incision was painted with collodion and covered with a gauze compress. The wound healed thoroughly without bulging. It is now thirty-five days after the operation and the child is in excellent condition.—*Archives of Pediatrics.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

New York, July 21, 1906.

PREOPERATIVE THROMBI AS A CAUSE OF POSTOPERATIVE COMPLICATIONS.

THE pathology of thrombosis and the dangers of resulting embolism have been very carefully studied and are now quite thoroughly appreciated by the profession. Thrombophlebitis is known to be a common occurrence in inflamed areas and also after extensive contusions and lacerations of the soft parts, and as these areas are frequently the site of operative procedures, the danger from embolism is necessarily increased. Attention is called to this fact in a recent communication by A. W. Abbott in *Surgery, Gynecology, and Obstetrics* for March, 1906. Although the risk of embolism, especially pulmonary, is well recognized, how far, he asks, does this knowledge affect our methods, and is there any practical manner in which these dangers may be minimized? He believes that many cases of sepsis, pulmonary embolism, and particularly many so-called cases of ether pneumonia, may be ascribed to the infection of a clotted vein or its disturbance by rough handling. In addition to these he also alludes to pyemia, abscess of the liver, and osteomyelitis, as other evidences of metastatic infection from the same source.

The only branch of surgery in which any special attention has apparently been given to this subject is that dealing with the diseases of the ear, and aural surgeons have formulated a definite operation for thrombi of the lateral and sigmoid sinuses. This consists of ligation of the jugular vein and clearance and drainage of the sinuses, and although difficult and usually done in desperate cases, it has proved eminently successful. Abbott claims that a similar course should be pursued in all operations complicated by thrombosis, but points out at the same time the difficulties connected with the application of such a procedure. Thus in the gastric and hepatic regions the thrombosed veins are likely to be hidden by adhesions or by the organs themselves. The renal, the mesenteric, the iliac, and the epigastric veins are likewise difficult of access, and thromboses complicating lacerations and contusions are also generally deep down in the tissues out of sight, if not out of reach. In operations for new growths, obstructive conditions, perforations, and wounds of the abdominal cavity, thrombosis may be more readily detected, and the same is true of operations in the peritoneum.

The rule may be laid down that in cases in which the collateral circulation is adequate, the thrombosed veins should be excised or ligated centrally; if the circulation is inadequate it is better to excise the veins with the adjacent necrosed tissue. If neither of these methods can be adopted, the entire region affected should be manipulated as little as possible, for fear of disturbing the clot or infecting the same.

As the author himself admits, the results have not always been satisfactory even when these rules are followed, although in most cases the outcome has been favorable. Renewed attention is directed, however, to the gravity of the condition by this and similar communications which have lately appeared and from which it is evident that extreme precautions must always be taken to avoid if possible the production of these dangerous and often fatal surgical complications. Abbott also refers to the fact that in certain cases it may be of value to recognize during an operation a puriform thrombophlebitis which cannot be controlled, for as this will usually prove fatal, it may be well to be prepared and to prepare those immediately interested in the patient for the inevitable outcome, so that the onus may be taken from the operation itself.

MATERNAL MORTALITY IN TENEMENT HOUSE OBSTETRICS.

"THE days may come and the days may go, but babies come forever," is the manner in which a famous couplet may be paraphrased in accordance with what takes place in some of our thickly populated tenement districts. No fear of race suicide will hold after a walk through some of the streets in these sections, and the frequency with which parturition occurs would naturally lead one to inquire how often a process which is always fraught with some degree of anxiety and fear terminates without fatalities. For many will contend that pregnancy and labor are physiological processes which, if left to themselves, will terminate without fault or error. That may be true to some extent under primitive conditions, but at the present day no one can deny that there are many disturbing factors which enter into the process aside from the pathological complications which we may or may not have been able to control. With the advance of obstetric knowledge the mortality among parturient women has markedly declined, so that even among the most adverse circumstances the death rate from childbirth will be found to be very low. In this connection some interesting figures are presented by J. A. Harrar (*Bulletin of the Lying-In Hospital,* March, 1906), who has studied the question in a very large number of cases of tenement house confinements conducted by the staff of one of our largest maternity hospitals. The work was done amidst all degrees of filth, misery, and poverty, but a death rate of but 0.357 per cent. in over 32,000 deliveries can only be regarded with satisfaction. It is to the underlying principle of intelligent supervision that these good results must be attributed, and efficient prophylaxis is nowhere of greater value than in obstetrics.

It is interesting to study Harrar's figures somewhat in detail. There was one death to every 280 deliveries, and the most frequent causes were sepsis, rupture of the uterus, eclampsia, and placenta prævia. Twenty-seven women, or about one in 1,200 cases succumbed to septic infection, and this is apparently the most serious factor now as formerly. The difficulty of securing even ordinary cleanliness

in the lying-in chamber, the ignorance of the patients, and the squalor of their surroundings no doubt enter into the situation, and it seems marvelous that they do not do so to a larger extent, for opportunities for septic infection are undoubtedly numerous. Another element of danger is the omnipresent midwife, who is stated to be always on hand in the capacity of nurse and general adviser, and may have conducted the labor in some cases until the appearance of a complication beyond her simple resources impels her to send for the hospital doctor. In Europe the constant endeavor has been to elevate the standard of these midwives, but in this country no restriction seems to be in force which limits or defines their field of activity.

Next to sepsis, rupture of the uterus was the most frequent cause of death; fifteen women succumbed to this accident, among the series noted, and thirteen deaths were due to eclampsia; placenta prævia ended fatally in twelve cases, and the remaining deaths were caused by a variety of other conditions. The entire mortality rate is relatively low, and the fact that almost one-quarter of the deaths were due to sepsis indicates in which direction a possible future reduction in the death rate may be hoped for.

BANKOK—A SANITARY PARADOX.

The healthful qualities of a city have been customarily gauged by the character of its natural environment and by the efforts which the municipality may make to supplement this by suitable sanitary arrangements. Where these have been neglected, it is expected that the general health of the inhabitants will be impaired, and this ordinarily in proportion to the extent to which the laws of sanitary living have been violated. It would be expected, therefore, that in a community where the environment is conducive to the spread of every form of disease, and where absolutely no effort is made to combat this tendency, the health of its inhabitants would correspondingly suffer. Any other view would be paradoxical, and yet the condition just noted is practically a picture of what exists at Bankok, in far eastern Siam, the home of the famed white elephant. Bankok is situated at the mouth of a large river, has a population of about three-quarters of a million, and is surrounded by low, marshy country. According to R. H. Bremridge, writing in the *Journal of Tropical Medicine* of April 16, 1906, it has a mean temperature of 83.5° F. and a rainfall of 46.5 inches. The large areas of smooth, stagnant water provide ample breeding grounds for hordes of mosquitos, among which are many anopheles. Everything would seem by nature to provide for malaria, and yet there is apparently very little in the city itself. There are no laws or regulations for the care of the public health. Open drains receive all the sewage, and the canals into which they empty furnish most of the water supply for the houses. In spite of all this, typhoid fever is not a common disease, and cholera, although always present, does not assume the proportions of even a moderate epidemic. Plague also has recently appeared, but has not spread as it was feared it would.

To any one with certain well fixed notions about sanitation this eastern city would appear like some dreadful nightmare, but, according to Bremridge, there is not much disease there, and the general appearance of the Europeans is more healthy than in many better cared for and better located places. It would seem that to combat properly the condition here represented nothing else would do than the complete destruction of the city. Any partial European system would fail to accomplish good and might be productive of harm. The writer wisely concludes that there must be some sort of a natural balance set up between the contending microorganisms and that in the fight for existence among themselves they are protecting the human species. To disturb this natural arrangement may mean disaster just as it has in numerous other instances.

But although this sanguine view may give satisfaction to those immediately concerned, there is no telling what the future may bring forth. In its present condition, Bankok cannot remain otherwise than a volcano of disease, ready to produce an eruption at any time when the proper incentive is at hand. As the means of communication grow more complete and extensive, the world necessarily becomes smaller year by year, and although Bankok is apparently too far away to do us any direct harm, its very presence contributes to a certain feeling of nervousness and apprehension.

MEDICAL EXPERT TESTIMONY.

The so-called insanity experts are coming in for a good deal of ridicule just now anent a case of alleged malingering by a wife murderer, in which the defense made out an excellent case of insanity by the aid of some of the most prominent of these experts. The man was sent to the asylum for insane criminals at Matteawan, and there recovered after a time. His cell-mate in the prison where he was confined until his trial was completed, is said to have testified that the man was shamming, using some sort of an application to the skin to make it dry and rough, going without food and sleep in order to make himself weak and nervous, schooling himself to endure sudden pinpricks without wincing, and acting the part of a fool whenever in the presence of others. The testimony of the man's fellow prisoner is not of much value, the only point in confirmation being that the alleged dement did not attempt to overthrow it, but promptly pleaded guilty to manslaughter in the first degree, and was sentenced to nineteen years and ten months in the penitentiary. The *Times* has published interviews regarding the case with three alienists, two of whom maintain that the man was insane at the time of his first trial, though admitting that he may have recovered, the third asserting that he was shamming throughout; thus sustaining the unfortunate reputation of experts, medical and nonmedical, on and off the stand, of often disagreeing.

Whether this criminal was or was not insane at the time the experts pronounced him to be so, we have no means of knowing, and the question is one of no particular importance, not even to the reputation of the alienists concerned. They are known to be honest men and competent specialists, and they doubtless would be the last to pretend to infallibility.

and to assert that they could never be mistaken in their diagnosis. It is the lawyers who set up this claim in murder trials and seek to convince the jury that diagnosis is an exact science. The physician knows that the contrary is the case, that mistakes are made daily by the most competent of diagnosticians, and in cases not only of supposed mental alienation, but even of the ordinary diseases of the body. It must be confessed that some experts foster this erroneous belief by the positiveness with which they give their testimony, though the contention is disproved by the equal positiveness with which they dispute the findings of the experts on the other side, who may be men of like attainments and reputation with themselves.

It has been contended that expert testimony would be more trustworthy and more serviceable in furthering the ends of justice were the witnesses paid by the State, and not retained by the lawyers of one or the other side. We doubt whether this would prove to be an effectual remedy, for the suggestion is based upon the uncomplimentary assumption that all experts are dishonest, or at least that their judgment can be warped by the fact that they are paid by the side in whose favor their testimony is to be given—an assumption which is, of course, untenable. It would, however, be better for the experts themselves, for, while their fees would probably be smaller, their testimony would be free from the suspicion of bias. But it would not make them more skillful diagnosticians; the findings of the different witnesses would be no less discordant and no less liable to be wrong. The one remedy lies in the instruction of the public and of the jury that the so-called experts are practitioners of an inexact science, more experienced and more instructed in their particular line than the average man, but nevertheless human and subject to err in observation and in judgment, and that undue weight should not be given to their testimony in doubtful cases.

The Functions of the Omentum.

Those who have frequent opportunities for inspecting the human abdominal viscera *in situ*, that is, pathologists and surgeons, are well accustomed to seeing great diversities in the size, form, and position of the omentum. It is not astonishing, therefore, that many different views are held in regard to a structure presenting so many variations. One of the most plausible theories regarding the use of the omentum is that, owing to its very abundant supply of large blood-vessels which are capable of great dilatation, it is able to serve as a regulator of the abdominal blood distribution, and Witzel, for example, estimates that one-quarter of the visceral blood supply of the abdomen can be contained in the omental vessels. This great vascularity also suggests another possibility, viz., that the omentum may to a large extent be the source of the abundant abdominal accumulations of serous fluid encountered under so many conditions. Such authors attach importance to the mechanical advantages attending the presence in the abdomen of a freely movable mass of tissues which can serve as packing material, as it were, to fill up chinks between the other viscera, and it has also been suggested that the omentum is of use in limiting the spread of infectious processes from one region of the abdomen to another. It has been found that the serosa of the omentum as well as of the diaphragmatic region has greater absorptive qualities than that of other portions of the abdominal interior, and when a little lamp black is thrown into the abdomen of an experiment animal the heaviest deposits are later on always found in these situations Numerous experiments have also been carried out to demonstrate the power of the omentum to assist in the repair of injuries and to dispose of dead material. Wounds of the uterus or bladder in dogs can undergo spontaneous repair through omental adhesions, and the spleen of rabbits cut from all its attachments but left free in the abdominal cavity can be caused to disappear completely through the same agency. The absorption of the splenic tissue is apparently effected through the agency of the phagocytes given off by the omentum, whose endothelial cells assume the rôle of macrophages, and a "phagocytopoietic" function has also been ascribed to this hardworking membrane which thereby becomes endowed with bactericidal powers. Schiefferdecker (*Deutsche medizinische Wochenschrift,* June 21, 1906), who is one of the most recent writers on the subject, explains this propensity of the omentum to attach itself to wounded areas or to fold itself about such a structure as the detached spleen, whereas it does not contract adhesions to healthy organs, by assuming that the omentum is secured to the raw surface of the exudation of fibrin that always follows the injury, Whether or not one accepts all of these various offices of the omentum, it seems probable that it has very decided functions and that it is distinctly a protective organ. This is also suggested by the fact that the horse, which has a very poorly developed omentum, is more prone to peritonitis after perforating wounds or operative procedures than are any of the other domestic animals.

English as She is Wrote at International Medical Congresses.

The wisdom of holding international congresses of medicine is often questioned, and among the numerous objections to their scientific value the linguistic problem occupies the foreground. Although most medical men of the present day are familiar to a greater or lesser extent with one or two languages besides their own, this knowledge serves them only slightly in a congress where several tongues may be requisite to represent the nationalities of all the participants. All efforts to introduce a universal language, even for commercial purposes, have unfortunately resulted in failure, and it would appear from certain efforts made at the last medical congress that all that can be hoped for is a definite agreement as regards technical terms. A German medical man had taken it upon himself to construct for the benefit of his colleagues at the Lisbon meeting a table of equivalent obstetrical terms which included those in ordinary use in Latin, Greek, French, German, English, and Italian. We cannot undertake to vouch for the accuracy of the other languages, but the author's success in dealing with the English expressions was not brilliant. A few examples picked at random from this table make one wonder whence the industrious author obtained his ideas regarding the English equivalents of well-known obstetrical expressions. Thus, triplets are referred to as "three-twins," the umbilical cord is called a "caul," mobility is "movableness," an umbilical murmur is a "hiss of the navel string," and the fetal heart sounds are "throbs of the heart"; a

bimanual examination is called "combined inquiry," the undilated cervix is referred to as an "impervious mouth." No user of English, we are quite certain, would recognize an hydatid cyst as a "moon calf" or "gastrotomy with removal of the pregnant uterus" as the well-known Porro's operation. Then, again, interlocked twins are spoken of as "twisted" and hydrocephalus as "watery head." A craniotomy is, according to this linguistic obstetrician, a "cephalic carve," and a perforator is a "dagger." In addition to these there are numerous other examples of how our language may be foully dealt with, and it must have been amusing to converse with any of the delegates unlearned in English who were compelled to rely on this "Obstetrical Baedecker" for their guidance.

Pernicious Advice from a Cabinet Officer.

The Secretary of the Treasury has recently published a circular, addressed to the bankers of the country, which may be sound financially, but betrays in the author a lamentable and almost incredible ignorance of sanitary first principles; it must be ignorance, for we cannot conceive that, knowing the evil of what he recommends, he would dare to suggest it. He advises the issue of a larger proportion of national bank notes of low denominations, alleging that the circulation of these notes is of longer duration than that of the hundred-dollar or thousand-dollar bills. So far, what he counsels is good, though the reason he gives for such counsel is bad; but he goes further, and requests the bankers to keep the bills in circulation as long as possible, and not to send them in for redemption "until unfit for use." To a banker with normal hygienic sense, the results of this advice would not be bad, for he would regard every soiled note deposited in his bank as "unfit for use," but this is not the interpretation the Secretary would have the readers put upon his work; he evidently means that the notes should be reissued and kept passing from one dirty hand to another, until the filth conceals the figures and the substance of the note threatens to dissolve away. What would be thought of an economist who, because laundry work costs money, might advise against a change of flannels, urging that they be worn continuously "until unfit for use?" Secretary Shaw needs instruction.

News of the Week.

Quarantine Regulations.—An amendment to the quarantine regulations applying specifically to all parts of the United States below the southern boundary of Maryland, has been issued by Secretary Shaw, with the object of enabling the fruit steamers to land their cargoes without detention. Under the new rules vessels are allowed the alternative of remaining out of the United States ports until five days from the time of leaving the infected port have elapsed or of making a change of crew. In the latter case the ship is permitted to enter as soon as the crew, except the master and chief engineer, have been removed from the vessel, placed in the quarantine station, the living quarters of the vessel thoroughly fumigated and a new crew placed on the vessel. Immediately after unloading all parts of the ship are required to be simultaneously fumigated for the destruction of mosquitoes. After this, loading is allowed, and the relief crew remains on the vessel until the quarantine station is reached, where the old crew goes aboard. The members of the relief crew are compelled to remain at the quarantine station until the arrival of another vessel or until relieved by the quarantine officer. Two sets of living quarters are to be kept at the quarantine station for the incoming and relief crews, and both quarters must be thoroughly fumigated immediately after being vacated.

Impure Foods.—The report of the New Hampshire State Board of Health, published July 14, declares that of 408 samples of prepared food products examined 186 were found to be adulterated, misbranded, or below the standard. These samples include canned meats, milk products, jellies and preserves, catsups and table sauces, and other articles. Nearly all of these articles, the report states, are manufactured outside of New Hampshire, but there is no legal way in which their entry into the State can be prohibited. Judgments have been entered in the Circuit Court of Lexington, Ky., against several sausage manufacturers and jobbers for selling adulterated products in violation of the Kentucky pure food law.

The Tuberculosis Campaign in Chicago.—A campaign to secure funds for the treatment of tuberculosis in Chicago was planned recently at the bimonthly meeting of the Executive Committee of the Chicago Tuberculosis Institute. Although efforts are being made to secure donations for summer camps and other means of treatment, the physicians and societies interested in the work pin most of their hopes for adequate funds on the charter legislation. A committee, consisting of Dr. Henry B. Favill, Dr. Frank Billings and Mrs. Lenora Hamlin, of the Institute, was appointed to confer with the charter convention with regard to additional revenue for the Department of Health. The Institute has raised, through the auxiliary committee, $1,000 for a summer camp, but has been obliged to abandon its plan of having tents in one of the parks, the South Park Board having very properly declined to listen to a proposition to that effect.

Health Pamphlet Issued by the Illinois State Board.—The Illinois State Board of Health has issued a new pamphlet, written on the same general lines as one published last summer, containing information on how to take care of the babies. Suggestions are given for the nursing mother, artificial feeding is fully discussed, and the advantages and disadvantages of the various infant foods are carefully considered. This pamphlet is issued for gratuitous distribution, and those who wish copies should apply to Dr. James A. Egan, Secretary of the Board, at Springfield, Ill.

Vital Statistics of Philadelphia.—For the week ended July 14 there were reported to the Philadelphia Bureau of Health a total of 539 deaths, as compared with 651 for the preceding week and 548 for the corresponding week of the previous year. Of this number 178 occurred in children under the age of one year, while there were 9 among persons between 80 and 90, and 1 in a person between 90 and 100. Diarrhea and enteritis were responsible for 115 deaths among children under the age of 2 years. Sixty-four deaths were due to tuberculosis of the lungs, 35 to Bright's disease, and 32 to heart disease. Four hundred and fifteen of the deaths occurred in natives of the United States and 115 in foreigners.

Crude Petroleum for the Plague.—Press dispatches announce that Dr. Turner, Health Officer of Bombay, has reported great success in the use of crude petroleum as a disinfectant against bubonic plague.

Telephone Consultations.—As the result of suit brought by a Viennese physician against a patient who refused to pay for professional advice given over the telephone the court decided that such consultations must be paid for as though held in the ordinary way.

Resuscitation of the Drowned.—The superintendent of the Third District of the Life Saving Service has reported a remarkable case of resuscitation after a prolonged immersion under water. The case is that of a man who was thrown into the water off the coast of Rhode Island on July 4 by the capsizing of a boat, and, according to the official report, remained under water for twenty-three minutes. Artificial respiration was kept up for an hour and forty-eight minutes before the first signs of returning consciousness were noted, and the patient did not recover complete consciousness until the following day.

Bellevue Hospital Training School.—The Aldermen's Finance Committee has reported favorably on the appropriation of $628,000 needed for the erection of a training school for nurses at Bellevue Hospital, and also on the appropriation of $2,000,000 for new police station houses.

Bequests to Charity.—Among the charitable bequests in the will of George J. Laighton are allotments of $5,000 to the Brooklyn Orphan Asylum Society, and $3,000 to the Brooklyn Home for Consumptives. By the will of the late Monroe B. Smith the sum of $50,000 is bequeathed to the Red Bank Sanitarium, a charity founded by the testator's father for the purpose of affording poor children opportunity during the summer of securing an outing and a ride on the river.

Smallpox on the Isthmus.—About twenty cases of smallpox have been reported from the Canal zone, but the disease has been mild in type and no deaths have occurred. The patients have all been negroes living in Colon.

Dr. James L. Greene of the Nebraska State Hospital, at Lincoln, has been appointed Superintendent of the Illinois Eastern Hospital for the Insane, and will assume charge at Kankakee within a few weeks. Dr. Greene's experience comprises fifteen years in dealing with inmates of institutions for the insane.

Dr. J. R. Rathmell of Chattanooga has been appointed to the chair of Theory and Practice of Medicine in the Chattanooga Medical College, in succession to the late Dr. Cobleigh, whose death occurred last year.

Officers of the Chicago Physicians' Club.—At the annual meeting of the Physicians' Club of Chicago, held June 26, the election of officers resulted as follows: *Chairman,* Dr. William T. Belfield; *Secretary,* Dr. Charles L. Mix; *Treasurer,* Dr. A. M. Corwin.

Lake Keuka (N. Y.) Medical and Surgical Association.—At the seventh annual meeting of this society, held at Grove Springs, Lake Keuka, the first week in July, the following officers were elected: *President,* Dr. J. E. Walker of Hornellsville; *Vice-President,* Dr. F. Driesbach of Dansville; *Secretary and Treasurer,* Dr. H. B. Nichols of Pulteney.

Death of Dr. Schaudinn.—Dr. Fritz Schaudinn, Director of the Department for the Study of Protozoal Diseases of the Institute for Tropical Hygiene in Hamburg, died of heart failure on June 22 at the age of thirty-six years. He was a pioneer in the study of protozoal diseases and was the discoverer of *Spirochæta pallida.*

Too Much Sanitation.—For months after Col. Gorgas took charge of sanitary matters in the Canal zone the chronic fault-finders were vociferous in their complaints that his efforts were fruitless. The task was too much for him, they said, and yellow fever and malaria would kill off every American who ventured into that plague-stricken region. The yellow fever disappeared and the malaria was subdued, and now the cry goes up that the Jamaica negroes are being decimated by pneumonia in consequence of the insistance upon ventilation of their cabins.

Obituary Notes.—Dr. Ezra D. Bemiss of Newark, N. J., died suddenly of heart disease on July 11 at the age of forty-three years. He was born in Canada, and had practised in Newark about twenty years.

Dr. Charles A. Tinker of this city died suddenly of heart disease at Westhampton Beach, L. I., on July 11, at the age of fifty-one years. Dr. Tinker was a native of Mystic Bridge, Conn., and was graduated from the New York University Medical School in 1878, since which time he had practised continuously in Harlem.

Dr. Albert H. Taft of Winchester, N. H., died on June 25 at the age of sixty-nine years. After serving through the Civil War, he received his medical degree from Bowdoin College. He practised first in Hancock, N. H., but removed to Winchester in 1873, and had remained there ever since.

Dr. Wm. G. Houtz of Lincoln, Neb., died on June 30 at the age of sixty-six years. He received his medical education at Girard Medical College and practised for many years in Troy Grove, Ill. He removed to Lincoln in 1881, and had practised there ever since.

Dr. George Cassel of Hartford City, Ind., died on July 2 at the age of sixty years. He was a graduate of the Ohio Medical College, but retired from active work some years ago.

Dr. J. A. J. Patterson of Liberty, N. C., died on July 6 at the age of sixty-five years, after an illness of several months.

Dr. Julia Wallace Russell of Concord, N. H., died on July 3 at the age of sixty-three years. She was active in the founding of the New Hampshire Memorial Hospital for women and children.

Dr. Paul Shekawana of Iowa City, Ia., died on July 7 as the result of injuries received in a trolley car accident. He was bacteriologist of the University of Iowa and the State Board of Health.

Correspondence.

"FITTING GLASSES," THE DIAGNOSIS OF ERRORS OF REFRACTION, THE INFLUENCE OF EYESTRAIN, ETC.

To the Editor of the Medical Record:

Sir:—Fearing that the many erroneous statements made in the article of Dr. A. Edward Davis, in your issue of June 30, 1906, may mislead the incautious, I beg for space to point out what seem to me the more important. With one exception almost every position taken is in part or wholly wrong, so that the hackneyed story of the dictionary definition again applies: The crawfish is not red, it is not a fish, and it does not walk backward. Many considerations compel too great brevity on my part:

1. The very title of the article is inaccurate. By all oculists and opticians it is common to speak of "the fitting of glasses" as a part of the optician's art, having nothing to do with the diagnosis of errors of refraction, with eyestrain, or with its systemic effects.

2. The epitome of the history of the discovery of glasses, of astigmatism, and of other refractive errors, of the *theory* of physical and physiologic optics, is made up of many sins of omission and commission; it has been frequently done, and better done, than here, and was not at all necessary to introduce the real subject.

3. The ophthalmoscope is made much of as a method of diagnosing refraction errors, but is of no use to those who

value scientific precision in such work. It has had almost no influence in "placing the subject of refraction on a sound basis."

4. The ophthalmometer is credited with even a greater rôle in "the science and art of fitting glasses." All skilled oculists are agreed that at best it is only an aid, never solely to be relied on. I myself find it of no use whatever. The article confesses this, unwittingly, of course, in the statement that it will, "as a rule," give the astigmatism to within an error of 0.50 D. Within that error, however, lies the work and success of the careful refractionist. Relief of eyestrain and its systematic effects depend precisely upon eliminating this astigmatism of 0.50 D. It is perfectly plain why those who do not eliminate this small degree of astigmatic error jest at the "extremists" and "exaggerators," and the "eyestrain faddists." The "hobby-rider" who does correct the neglected 0.50 D. and less of astigmatism cures the reflexes of his patients, and, naturally enough, emphasizes the truth.

5. Retinoscopy is the most accurate and trustworthy objective method of diagnosing errors of refraction. The article I criticise discourages the method, because it requires carefulness, time, and conscientiousness on the part of the oculist. But what is the oculist "here for"?

6. The epitome of the history of the discovery of reflex ocular neuroses is all wrong, even as to the dates and references. It is a sorry jumble of inaccuracies and misstatements. It seems designed only to deny and ridicule the theory of the very existence of systemic diseases due to eyestrain. It ends with a quotation from the Prophet of the god, *Ophthalmometer*, that "the belief in any morbid constitutional condition" due to eyestrain is nonsense. Although this is surpassingly frank and brave, it is itself most amusing nonsense. Hundreds of capable oculists and general practitioners smilingly demur to the ignominious implication. The quotations from Fisher, Sachs, Dana, and others are in these times delightfully funny. One hopes they will be repeated many times in the future, because getting such "scientists" on record is a great desideratum. When the "flop" comes it will thus perforce be all the more evident and mirth-provoking.

7. Excessive space is given to the summary of Dr. Howe's charming article. Unfortunately, neither the quoter nor the "collective investigator" gives the names of those who reply to the *questionnaire*. The names of those who scorned to reply to such an absurd "investigation" are also wisely and equally omitted. Were it not that so many are put on record, the whole pother has not the value of the paper on which it was tabulated. If your contributor knew several things about it, even he would realize how much less valuable it is than that blank foolscap page.

8. Your contributor's article has another indirect merit: it exposes the "science" and "art" of many who are doing refraction work. Its chief motive appears to be to deny the advisability of the use of cycloplegia in the diagnosis of refraction errors. But all who know, know most certainly that there can be no accuracy in such work without what the author calls a score of times, *cyclopegia*. This is the crowning proof of the author's supreme abandonment of all reserve: he makes the unblushing plea that refraction as practised nowadays "comes nearer to being an exact science than any other branch of medicine." In fact and in truth, we all know it to be the most inexact. The author himself forgetfully admits and reemphasizes the truth that few or no oculists do agree in their diagnoses and prescriptions.

9. Patients go to opticians, it is said, chiefly because the bad oculists persist in using "cyclopegics." I should say it is because they don't use them, and because the optician can do as good work (*gratis*, too) as oculists do who do not use "drops," and who scorn 0.50 D. (and often much more) of astigmatism. Your contributor is in naïve innocence that modern ophthalmology does not disable a patient "ten days," nor "three days," not even one day. In eighty minutes after a patient enters the office he may be completely cycloplegicized, accurately refracted, and the accommodation and pupils wholly normalized.

10. One of the most inexcusable blunders made by your contributor is the exasperating mixings-up and indiscriminations in crediting men with service in bringing about progress in the science and art of refraction. Men are credited and honored for work they did not raise a hand in doing; others who labored mightily are wholly ignored. Men may be made the heroes of discoveries and reform in refraction who have always scorned and still despise refraction; who "cure by taking all glasses off"; who detest "cycloplegia"; who, until very recently at least, sent their patients to the optician to be refracted; who to-day would "not bother about a little astigmatism."

GEORGE M. GOULD, M.D.

PHILADELPHIA.

OUR LONDON LETTER.

(From Our Special Correspondent.)

ABDOMINAL SECTION—TYPHOID AND HOSPITALS OF ASYLUMS BOARD—DIPHTHERIA—CITY COUNCIL AND COUNTY COUNCIL ON FOOD INSPECTIONS.

LONDON, June 29, 1906.

DR. Ranken Lyle has communicated to the Gynecological Society a series of fifty consecutive abdominal sections performed at Newcastle, between October, 1903, and January, 1906. There are only six beds in his hospital, and the operations are performed in an ordinary attic, not specially fitted up. He had only one death to report in the series. His technique he reported as the simplest, as he was of the opinion that complicated methods and elaborate preparations were unnecessary and might prove sources of danger by leading sometimes to some essential being overlooked. Antisepsis was carefully carried out, hands and forearms being thoroughly washed in hot lysol solution with a nail-brush, turpentine and methylated spirits then being used and washings with corrosive sublimate 1 in 1,000. Instruments were boiled and put in 1 in 40 carbolic solution. Sponges were of gauze, boiled for 20 minutes and wrung out of hot normal saline liquid. All buried ligatures were of catgut, prepared with ether, methylated spirit, and sublimate. Silkworm gut was used for all superficial sutures. The abdomen was prepared the previous night by washing with soap and water, then sponging with turpentine and methylated spirit, followed by a sublimate pad. Just before the operation it was washed with sublimate solution 1 in 1,000. No vaginal antisepsis was employed, even for panhysterectomy. Incisions were as short as consistent for the operations, which accounted for absence of shock and diminished risk of hernia. All cut peritoneal surfaces were accurately adjusted. The abdominal wound was closed in three and sometimes four layers in order to adjust corresponding structures. A strip of gauze, wrung out of hot saline and covered with plain absorbent wool, was the dressing, and this was kept in position by strapping and flannel bandage. In three cases of pyosalpinx a little purulent fluid escaped but was carefully mopped up and caused no trouble. Where a large raw surface of peritoneum occurred, as in ventral fixation, as much normal saline as possible was left in the abdomen, so as to float the intestines from the wound, with the view of preventing adhesions.

Dr. Lyle's after-treatment was equally simple. About three hours after operation a drink of hot water, with a little sodium bicarbonate was given, as it is often effectual in bilious vomiting. This was continued and barley water allowed until next morning, when a cup of tea was given, followed during the day by milk diluted with barley water or soda water. Early on the second morning, calomel, in two doses of 5 and 3 grains, at an hour's interval, and one-half hour later hot seidlitz mixture were given. As soon as the bowels were moved the patient was put on a liberal diet. Sutures were removed on the tenth day. Interesting details of cases were given, and Dr. Lyle offered the following points as desirable for securing good results: 1. Correct preliminary diagnosis. 2. Simple technique. 3. Simple antiseptic preparation with asepsis. 4. Use of few instruments and appliances. 5. Limited incisions. 6. Correct adjustment of all cut peritoneal surfaces. 7. Complete closure of abdominal cavity without any drainage. 8. Free use of normal saline when purulent material gets into pelvis or abdomen.

In the discussion Dr. Lyle was congratulated on his results, only one case having died, and that from a disease which could not be anticipated or prevented—pulmonary embolism on the tenth day.

Dr. Herman believed that septic poison was conveyed only by contact, and its particles being subject to gravity did not fly up to the operator's beard or hair. The only point was to make everything that touched the patient or the wound aseptic. If there were an abscess he would make some provision for the exit of pus; in several cases of extrauterine abscess he had used gauze for this purpose, putting it in the opening and so hindering union by first intention with satisfactory results.

Dr. Eden said diagnosis was too much neglected, and he was glad Dr. Lyle had emphasized its importance. He thought rubber gloves necessary in infective cases. He managed, as far as possible, his own instruments, to reduce the risk of others handling them. He found no harm in a gauze drain passed through a rubber tube; but the more experience he had of abdominal section the less he saw reason for drainage. He thought there was some risk of conveying organisms by filling the peritoneal cavity with saline fluid.

Dr. Elder thought sepsis after an operation must be due to infective material from outside. Few would go as far as Dr. Lyle in regard to drainage. Gloves interfered with the delicacy of touch, but were necessary in suppurative cases.

Dr. R. L. Dickinson of New York said he had been impressed with the simplicity and common sense of Dr. Lyle's methods. He thought in America there was a danger of having too many assistants in these operations: the training schools insisted on as many nurses as possible being admitted. He preferred doing his own work and giving assistants as little chance as possible of omissions in the antiseptic arrangements. Catgut was commonly used in America and the use of gloves was practically universal. The percentage of septic cases had fallen since gloves were generally used. He made the smallest incisions. The custom in America was never to drain, except for pus in the connective tissue.

Dr. Macnaughten Jones said the good of early operation was asepsis and nothing should be omitted to secure it. He indorsed free flushing in cases requiring it. The three most important points were temperature, pulse, and bowel. The last gave him most anxiety. Sepsis sometimes occurred in spite of every precaution—as Fritsch said, "The patient did not die because of sepsis, but became septic because he was dying."

Dr. Ryall could not understand how pouring fluid into the abdomen could prevent adhesions; they were best prevented by getting the bowels open early. He much preferred tube drains to gauze. He believed in masks to prevent talking, whispering, or spitting into a wound. The shorter the operation the better for the patient.

Mr. Bowreman Jessett, President, said an incision should be large enough to permit removal of a tumor without stretching and give a view of the pelvis. He always disinfected the vagina, as it might have to be opened in the course of the operation. The secret of success he thought was covering the stump by peritoneum. Sutures should be of catgut.

Dr. Lyle, in reply, said he had only two assistants, and only three or four students could stand in the room. He drained only in cases of pelvic abscess; in others he flushed the cavity and closed the wound. He thought the normal saline stimulated the circulation in the peritoneum and assisted the phagocytes. He did not think gloves necessary. Perhaps nobody talked more than he did when operating, but he had seen no ill effects. He did not think much of disinfecting the vagina; it was not usually septic. He was careful to flush out the pelvis and wash away the pus.

At yesterday's meeting of the Common Council of the City a report from the Health Committee recommended representations to be made to the local Government Board, urging the necessity of forthwith promoting legislation for the compulsory inspection by experts of all animals intended for human food just before slaughter, and all meat free from disease after inspection to be officially stamped. Further, imported food to be subjected to the same tests, and that meat packed in a way to prevent inspection should be excluded from the United Kingdom. Private slaughter-houses were recommended to be abolished. An objection was raised to hurried legislation on account of the vast importance of some of the issues raised in the report, and the discussion was adjourned, the committee being asked to report on the existing inspection in the central markets.

In the House of Commons the President of the Local Government Board, in reply to a question, said he did not see any use in making surprise visits to English manufactories of food products. He was considering the question of a conference of local authorities as to cooperating.

On Tuesday the County Council met after the Whitsun recess and received a report from its Public Health Committee recommending application to Parliament for authority to establish public slaughter-houses and food inspection stations, and even to provide for the inspection of all food entering the metropolis. It is suggested that inspectors with veterinary and other qualifications would be required. It is said to be easy for a vender to avoid seizure by removing bad goods across the boundary of his district into the next, and therefore the disposal of unsound food goes on to an extent that would not be possible under a single efficient authority for the whole area.

The Asylums Committee of the Council has not abandoned the idea of superseding the workhouse lunacy wards by receiving-houses to be established by the council. Many guardians are opposed to this proposal, but the committee still advocates it, arguing that under such a system incipient cases would more likely be received and their disorder arrested, thus preventing long seclusion in the asylums.

A serious outbreak of typhoid fever in one of the newest institutions of the Asylum Board was reported to that body on Saturday and elicited some severe remarks on the steps taken to cope with the situation. Up to the 18th inst. fifty-four patients had been attacked and two attendants were in bed. Professor Smith and other members of the Board declared that the sub-committee had displayed strange inactivity and negligence. The gravity of the situation had apparently not been realized until the attention of the Local Government Board was called to it by the Urban District Council, when Dr. Copeman was at once sent to inquire into the circumstances and report. The chairman of the sub-committee defended it and said the outbreak was investigated, the drainage up to date, and the diet could not be the cause. The matter was referred to the General Purposes Committee to examine.

The mortality from diphtheria in the hospitals of the Board during the year was reported at the meeting as 8.3 per cent., the lowest on record, and this was regarded as due to antitoxin treatment. Professor Smith remarked that in 1823, the year before the serum was used, the death-rate among the patients was 30.4. At the Brook Hospital it was proved that if the remedy were used early there was not much fear of a fatal result, and the longer the delay before using it the higher became the mortality. It was to be held beyond doubt that they had a most potent remedy for diphtheria. One of the most satisfactory things done by the board during the eighteen years he had been a member was to make provision for producing antitoxin serum in its own laboratories.

OUR BERLIN LETTER.

(From Our Special Correspondent.)

A NEW SOCIETY—MILITARY SURGERY—GASTRIC ULCER—BIER'S HYPEREMIA—THE GERMAN ROENTGEN SOCIETY.

BERLIN, June 26, 1906.

A NEW medical society has been formed here, entitled the "Zwanglose Demonstrationsgesellschaft." It is planned to have fortnightly demonstrations of unusual cases and is intended especially to keep specialists in touch with other branches of medicine. The meetings are of great interest, but as they consist only of short demonstrations they are not suitable for reports in these letters.

As in former years, the last Congress of German Surgeons held at Berlin was the occasion of the presentation of many interesting communications. Three questions in particular were extensively discussed and were the subjects of many papers: military surgery, gastric ulcer, and the Bier treatment. The surgical experiences of the Russo-Japanese War were dealt with by many speakers. Zoege von Manteuffel of Dorpat said that the small surgical stations must be replaced by larger ones because the greater range of the modern small arms caused battles to be fought at greater distances. At the front flying columns are most effective, consisting of carts and pack mules. A large number of conveyances are necessary to keep up communication between the flying columns and the main surgical stations. The first aid should consist in the application of sterile bandages and the fixation of injured limbs. Only wounds of the cranium require immediate major operation to avoid meningitis, and liver wounds require tamponade; all other wounds, including those of the heart and thorax are to be treated expectantly. Schaefer of Berlin read a paper on the effects of modern firearms, in which he said that the battles of to-day were not more bloody than those of the Franco-Prussian War, but that the individual soldier underwent greater danger. The danger of gunshot injuries was greatest among the infantry and less so in the artillery and cavalry. The statistics of 36,000 wounded showed that the death rate was very small, and that more than half of the number were later on able to return to the front. Goldammer of Hamburg described his experiences in South African warfare, in which the battlefield is often very far removed from the possibility of surgical assistance. Even under these conditions the dry treatment of the injuries gave the best results, as well as the principle of touching the wounds as little as possible. Vettingen of Berlin emphasized the improvement in the prognosis of gunshot wounds of the abdomen since the use of projectiles of smaller caliber had become general. The intestines were more likely to escape injury and the track of the bullet was usually very small. For these cases the first rule was to avoid overtreatment, and laparotomy was justified only when injury of the gut was to be assumed, or on account of hemorrhage or prolapse of the intestine.

Krönlein of Zürich read the introductory paper on the surgery of gastric ulcer. He stated that the death rate immediately after operation had become greatly reduced,

and that the results of gastroenterostomy were very excellent because cicatrization of the ulcer was secured and the normal function of the stomach was restored. Excision of the ulcer should be performed only in rare cases, as the condition was usually multiple. Pyloroplasty and gastrolysis were operations which should never be performed. Resection of the pylorus for ulceration or stenosis in this region was justified only if carcinoma were feared. In the very animated discussion that followed such eminent surgeons as Kümmell, Lorenz, Kocher, and Braun took part and fully agreed with Krönlein in his preference for gastroenterostomy. Only Rydygier of Lemberg and Kausch of Schöneberg spoke in favor of resection of the ulcer as being easier to perform. Fiebig of Vienna had studied the question experimentally and observed on dogs the effect of the different operative procedures. He had found that in his experience the best results followed gastroenterostomy combined with enteroanastomosis.

Hals of Magdeburg opened the discussion of Bier's method of hyperemia, saying that it was useful not only in treating inflammation but also for infected wounds. The method was inapplicable in cases of erysipelas, thrombophlebitis and diabetic gangrene. Rotter of Berlin considered that the method was useless in osteomyelitis. Stick of Breslau advised drainage in connection with the method for mastitis. Danielsen of Marburg had found the method useful for the treatment of otitis, and Heidenhain of Worms for obtaining soft scars after operation. On the other hand the method had also some opponents. Lick of Hamburg reported cases in which pain and suppuration had been increased by it, and he considered that in streptococcus cellulitis the old treatment with a free incision was preferable. Owing to the fact that the method required the constant supervision of the physician it was applicable only in hospitals. Lexer of Königsberg believed that the hyperemia treatment should be used only for mild cases in acute affections, and that in more severe conditions it should be preceded by free incision. The unusually animated discussion in general bore witness to the effectiveness of the procedure in a number of cases of acute and chronic disease, and Bier himself in closing said that he had obtained the best results in most acute cases and especially in acute inflammatory processes.

At the second congress of the German Roentgen Society a number of papers were read on methods for measuring the rays, but no practicable means for this purpose were suggested. Levy-Dohrn of Berlin pointed out that the difficulty in this direction lay in the irregularities in effectiveness of the apparatus, the quality of the tube, the variety of the rays, and the size of the field to be influenced. Grashey of Munich considered it important not only to differentiate soft and hard tubes, but also to ascertain the composition of the gas within the tube. Stegman of Vienna said that he had often seen very great effects produced by the smallest doses, and he considered that the individuality of the patient was the greatest factor, so that accurate estimation was not always possible.

Several interesting papers were read on the subject of *x*-ray diagnosis. Grummath of Berlin described the use of small tubes made for introduction into the mouth for the purpose of determining the nature of various affections of the teeth and maxillæ. Albers-Schönberg of Hamburg discussed the sources of error in the diagnosis of renal and ureteral calculi and referred to such misleading structures as calcareous myomata and phleboliths. Graesner of Cologne showed radiographs of a case of osteomalacia, scoliosis, and fracture of the vertebræ which demonstrated the close connection between osteomalacia and rachitis. Pictures were also shown proving that fractures of the lumbar vertebræ could be caused by very slight degrees of force.

In a paper dealing with the therapeutic application of the rays, Schmidt of Berlin said that he had obtained good results by their aid in cases of prostatic enlargement. Other investigators stated in the discussion that fibrous and cystic goiters were not affected by the Roentgen rays, whereas in cases of parenchymatous enlargement the gland apparently became smaller. Rosenberger of Würtzburg warmly advocated the use of the rays as an adjunct to surgical treatment in cancer, and spoke of a recurrent carcinoma the size of the fist which was cured in thirty sessions. Eberlein of Berlin said that he had cured with the Roentgen rays a case of polyarthritis in a chimpanzee.

A veritable sensation was caused by the demonstration of radiographs by Alexander Kesmarck of Buda Pesth which were remarkable for their plastic effect, but the author did not disclose the secret of the means of their production.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

EXTERMINATION OF PLAGUE-INFECTED RATS—PLAGUE IN HONG KONG—A TIDE IN AN ARTESIAN WELL—NEW SANITARY CODE FOR MANILA—PERSONAL NOTES.

MANILA, May 12, 1906.

THE bacteriological examination of rats caught in the city of Manila, for the purpose of ascertaining if they are infected with plague, has been carried out systematically since the first rats so infected were discovered, during the early part of March. It will be remembered that it was reported at that time that not only the premises in which the infected rats were found, but the entire block in which the premises were located was treated just the same as though cases of plague had occurred in human beings. Active rat-catching has been continued in the districts which were infected. During the past three weeks no more plague-infected rats have been found, from which it would appear that the war waged upon these pests by the Bureau of Health had been entirely successful.

No cases of human plague have occurred in the city of Manila since April 20. From the foregoing it will be seen that the claims made by Kitasato and other Japanese physicians, that whenever plague-infected rats are found that human plague will follow within two months, was not confirmed by the local experience.

Hong Kong is apparently worse afflicted with plague this year than has been the case for some years past. From the first of January to the 19th of May, there were 491 cases with 461 deaths. Of these, 483 cases occurred among Chinese, with 456 deaths, 4 cases occurred among Europeans, with two deaths, and four cases with three deaths among other Asiatics. The actual number of cases of plague in Hong Hong is probably much greater than is shown by these figures, because it is customary for a Chinaman who is stricken with plague to leave Hong Kong at once for Canton or some other place, in order that he may avoid the disinfection of his house and other sanitary measures carried out by the health authorities. For the week ending May 19, 1906, 90 cases with 83 deaths were reported.

One case of plague arrived in Manila May 6, on a steamer from Hong Kong. The same was promptly isolated and treated at the San Lazaro Plague Hospital. The patient was a Japanese female servant who was en route from Japan to Manila, and was detained in Hong Kong awaiting the departure of a vessel for the Philippines. The disease was no doubt contracted at Hong Kong.

The artesian well which was bored on the island of Cauit, for the Cebu Quarantine Station, was completed a few weeks ago. Water was struck at a depth of 250 feet and is almost fresh, but a remarkable circumstance in connection with it is the fact that the water in the well rises and falls with the tide, yet the overflow of the well is always in the neighborhood of six feet above the level of the surrounding ocean. A biological examination of the water shows a very small number of bacteria, and no ameba or pathological protozoa.

The epidemic of malarial fever among the troops at Camp Stotsenberg, mention of which was made several weeks ago, is now entirely under control. Thorough screening of the infected cases, and prophylactic doses of quinine, were used in stamping out the scourge.

The Sanitary Code for the City of Manila has been under consideration by the Municipal Board for some months past and has now been printed in the shape of a proposed ordinance, and a public discussion will take place June 4, in order to give the people of the city an opportunity to express theselves with regard to it. The code is most complete in its character, and if passed in its present form it will be one of the most complete sanitary codes possessed by any American city.

The warm season this year has been one of the hottest that has been experienced in a number of years. For weeks at a time the temperature during the day has been between 96° and 100° Fahrenheit. In spite of the great heat, however, no sunstrokes have been reported, in fact, sunstroke in the Philippine Islands is exceedingly rare.

Dr. J. H. Biggar, Medical Inspector, Bureau of Health, left Manila May 5, for the United States, by way of Europe, on a six months' vacation.

Dr. W. A. Christensen, Medical Inspector, Bureau of Health, will sail for the United States on the transport due to leave here May 20.

Assistant Surgeon W. E. Ebersole, United States Marine Hospital Service, formerly stationed at San Francisco, arrived in Manila, May 11, and will take up the duties of boarding officer in the Quarantine Service at this port.

Passed Assistant Surgeon G. W. McCoy, United States Marine Hospital Service, has been relieved from further

duty in the Philippine Islands, and directed to proceed to San Francisco, and report his arrival to the Bureau in Washington, by wire.

Progress of Medical Science.

New York Medical Journal, July 7, 1906.

Treatment of Tabes in the Preataxic Stage.—The various drugs which have been proposed at various times are enumerated by A. D. Young. If silver nitrate is given, it should be taken for one month and then be suspended for ten days, or should be accompanied by arsenic to the physiological limit. Antisyphilitic treatment should be confined to those cases showing tabetic symptoms within two years of infection, and accompanied by luetic manifestations outside the nervous system. Mercury and the iodide may do much harm in non-specific cases. Mental and physical quietude should be most strongly insisted upon. The tepid bath is often of service, and the general discipline of hydrotherapeutic establishments is often of great service. Electricity is advised by Erb, whose directions for galvanism are to place a moderate-sized anode in the vicinity of the cervical sympathetic and a large cathode on the side of the vertebral column for four or five minutes, moving it from above downward. The faradic brush may be used over the skin of the back. Plain food, plenty of sleep, moderate amusements, avoidance of confining and monotonous occupation, all find their proper place. For the lancinating pains we may give the coal-tar products, methylene blue, salicylates, and bromides. Often only morphine will relieve, but care must be observed not to form a habit. Cocaine will relieve laryngeal crises, and suppositories of opium, iodoform, and belladonna may relieve bladder and rectal pains.

Automatic or Unintentional Suicide in an Epileptic.—A unique case is recorded by W. P. Spratling. The patient was a man of twenty-one years, his attacks alternating between grand and petit mal. After the latter he was invariably automatic for some minutes. On the morning of his death he was seen fifteen minutes previously thereto in good condition. When found, he was dead. His mouth and hands were stained with black ink, and an ink bottle of about two ounces capacity lay on a bed near him, with the cork out and less than half an ounce of ink in the bottle. The ink was of the kind used by architects on mechanical drawings. Its odor indicated the presence of phenol and aniline oil. It also contained nitrobenzol. The patient used it in his work in the Sloyd school at the Craig Colony. It was the impression at first that the patient had committed suicide by purposely drinking the ink; but further investigation led the author to believe firmly that he drank the ink while in an automatc amnesic state following a petit mal seizure. His father came to the colony a week later and said that on a number of occasions the boy had attempted to drink various improper things while in such a state following seizures. The author adds that many of the patients at the colony remain in automatic amnesic states anywhere from a few seconds up to two or three days, and even weeks after seizures of various types. During that time they are capable of performing acts of various degrees of complexity, with which they are familiar, but they are absolutely unconscious of what they are about, and it is his belief that while in this state they can do nothing new. When some are in this state and are spoken to quite loudly, they will answer briefly, but they will have absolutely no knowledge of the conversation afterward.

The Early Symptoms of Tuberculosis and How They May Be Developed when the Applicant Attempts to Conceal Them.—Ward Brinton considers this subject from the special point of view of the life-insurance examiner. He takes up in succession the symptoms of cough, hemoptysis, dyspnea, pain, fever, general appearance, and the matter of alimentation, in their significance to the matter of an early diagnosis, making suggestions to be followed in case the patient's answers are evasive and unsatisfactory. Too many details are given for reproduction here. Inquiry as to possible nasal catarrh may sometimes elicit the fact that the patient has the real dry hack suggesting incipient pulmonary trouble. Intermittent hoarseness is suspicious; so also a disposition to curtail the amount of bodily exercise, on account of the dyspnea thereby occasioned. Sometimes, as we question in this particular, the patient expands his chest vigorously and says he never gets out of breath, yet the very expansion may set up a tendency to cough. Pains about the chest are most suggestive. Most pleurisies are really of a tuberculous nature. It is difficult for the insurance examiner to get a line on the patient's temperature range, but the noticing by the latter of any undue warmth in the afternoon, flushing of the face, warmth of the palms, dryness of the lips, with a trifling respiratory increase and pulse rapidity, may be of significance. The insurance examiner is placed at a disadvantage with those who have been "coached" with regard to answering questions. The detection of slight degrees of the malady is often difficult, and not until a patient has been under observation for a long time and repeatedly examined can a positive diagnosis be made.

Journal of the American Medical Association, July 14, 1906

Treatment of Insanity in General Hospitals.—D. R. Brower for thirty years has been treating selected cases of insanity in the wards of general hospitals, with success sufficient to justify him in urging this plan on the profession generally. The method used is substantially the Weir Mitchell rest cure, and the cases specially amenable to this treatment are the autotoxic and exhaustional ones. For the progressively degenerative types the only proper place is the special hospital for the insane. The rest cure should be followed by judicious exercise, congenial occupation, etc. Details of the treatment are given.

The Bedbug as a Transmitter of Disease.—A. A. Girault reviews the facts so far as known regarding the agency of the bedbug in the conveyance of disease to man, and comes to the conclusion, with Nuttall, that nothing has yet been definitely proven. This insect is under strong suspicion as regards relapsing fever, leprosy, bubonic plague, anthrax, and tuberculosis, and the possibility of its agency in the spread of other diseases, such as diphtheria and syphilis, has been prominently suggested. Coplin has found that pure cultures of the typhoid bacillus could be inoculated from infected bedbugs, and Girault finds that they are apparently fully as greedy for the blood of mice, which are suspected of being the carriers of some diseases, as they are of that of man. He holds, therefore, that considerations of health and self-defense, as well as of decency and personal cleanliness, bid us exercise caution against this very objectionable parasite.

Negri Bodies in Hydrophobia.—D. J. Davis describes these bodies, discovered by Negri in 1903, and since found to be almost universally present in the protoplasm of the nerve cells and occasionally in the nerve processes of rabid animals, man included. The percentage of cases in which they are not found is very small, and he thinks that with more experience and improved staining methods it may be made still smaller. The sizes vary from quite large to almost ultramicroscopic, and the fact that the virus passes through the Berkefeld filter No. 5 does not exclude these bodies from being etiologically associated with the disease, as an ultramicroscopic stage of the organism may exist, as Volpino has held. They are usually oval or round, and have a distinct ringlike or rosette internal structure, although the smaller ones are generally homogeneous. They are strongly eosinophilic, but by proper staining basic staining granules are seen which are different from the ringlike structures. For fixing the tissues Zenker's fluid is best, but sublimate has also been recommended. Alcohol and formalin are unsuitable. Any of the ordinary stains, such as hematoxylin or eosin, bring the bodies out distinctly. Details of various methods that have been recommended are given. Davis points out their value in the diagnosis of rabies; they should always be sought for, the Nelis-van Gehuchten reaction of the proliferation of endothelial cells in ganglion cell capsules being also incidentally looked for. The test has several advantages over that by inoculation; it is quicker, is fully as reliable, and is longer available after putrefaction has set in. The ability to make the diagnosis accurately within a very short time is by itself sufficiently important. Little is known as yet of the true nature of these bodies, whether they are protozoa, as Negri held, or not. If they are degeneration products they are different from any that are so far known. They are specific for rabies and hence of importance as diagnostic structures.

Calcification of the Vas Deferens and Seminal Vesicles.—S. George reports a case in which a bony mass was found in the wall of the right seminal vesicle. He reports also a second case of calcification of the left vas deferens which, unlike the other, was not a regressive metamorphosis, but a calcification in connection with chronic inflammation, and very probably the result of gonorrheal deferentitis. Such conditions have little clinical significance, except that possibly in rectal examinations they may be mistaken for calculi or neo-

plasms in the bladder. From a theoretical point of view, however, they are of interest.

Locating Fistulæ.—H. A. Royster reports a case of fistula following celiotomy, the opening of which into the bowel could not be satisfactorily located on account of dense matted adhesions. All attempts to find the hole in the bowel were fruitless until, at last, at the second operation for the purpose of closing it, he had the nurse pass a long rubber catheter up the rectum, and with the abdomen still open, he injected an ounce of hydrogen dioxide. As soon as this substance reached the sigmoid there was an effervescence, indicating the location of the fistula, which was grasped with forceps and closed with successful and permanent result.

The Lancet, June 30, 1906.

Idiosyncrasy of the Skin in Regard to Mercuric Chloride.—In an Italian girl with submaxillary abscess, R. Bellantoni incised the latter, washing with a 1-1,000 solution of bichloride. A wet gauze dressing, the same solution being used, was bound on. The next day the skin of the axilla, adjoining thorax, and submaxillary region was scarlet red and covered with small pustules. The appearance was much like that of a burn of the first degree. Under cleansing with sterile water, bismuth applications, and dry sterile gauze the lesions healed in a few days.

The Nature of Surgical Shock.—W. Sheen reviews the various theories which have been put forth as to the nature of surgical shock, and finds that there are three distinct stages leading up to a fatal result: (1) Pressor impulses reach the vasomotor centers and are followed by contraction of arterioles throughout the body. At the same time the portal venous system relaxes. Both the arterial and the portal pressures are raised. (2) Depressor impulses reach the vasomotor centers, the arterioles throughout the body relax, but do not dilate, because there is no blood to fill them, remaining in a retracted condition. The arterial blood pressure falls. (3) The veins of the portal system and possibly other internal veins lose their tone. All the blood in the body collects in them and death follows.

Salicylate Poisoning in Children.—F. Longmead reports eight cases, two of which proved fatal. In the administration of large doses of sodium salicylate, symptoms of acid poisoning occasionally occur, suggesting those of diabetic coma, viz., drowsiness deepening into coma, with air hunger and finally death. The child is flushed, eyes are bright, and there is usually great thirst. Vomiting may precede the above symptoms, and the drowsiness may be replaced by or associated with delirium. In every instance in which it was looked for, acetone was found in the urine. In the more serious cases the characteristic sweet odor developed in the breath. No reaction was observed in the urine of patients taking salicylates who did not present poisonous symptoms. The author introduces the eight clinical histories with a table showing the variability of the dose of the drug sufficient to produce toxic symptoms, and presents the following conclusions: (1) Salicylate of sodium sometimes causes in children symptoms resembling the acid poisoning of diabetes. (2) The toxic dose is variable, depending on the idiosyncrasy of the patient and the presence or absence of constipation. (3) Acetone may be detected in the urine and in the breath, its presence constituting one of the first symptoms of the poisoning, and affording a valuable danger signal. (4) Treatment should be directed to keeping the acidity of the urine low and the bowels opened in cases of patients taking this drug. (5) If acetone is found or the urine gets more and more strongly acid, the salicylate should be omitted and alkali given alone.

The Nervous Phenomena Following Attempted Suicide by Hanging.—R. N. Hart reports the case of a man who attempted to hang himself and who was cut down after ten minutes' suspension by a large jack-towel. As he fell his head was knocked against the wall. In a few minutes he was seen by the author, who found him cyanosed, but breathing deeply and regularly at a normal rate. Pulse was 100, normal; pupils equal and pinpoint; he was unconscious, but there had been no escape of bladder or bowel contents. There was no evidence of skull fracture. For forty hours he remained unconscious, but four hours after the hanging his pupils dilated slightly, the right more than the left, both reacting to light. He gradually became quite stiff equally and simultaneously over his whole body, the reflexes being excessive and a marked ankle clonus being present on both sides; his plantar reflexes were both of the flexor type. He was then admitted to hospital, where his heart, lungs, and urine were found to be normal to physical examination; his pulse was 104 and his temperature was 99.4° F. He was still rigid, and his pupils were in the same condition; he had conjugate deviation of his eyes to the right, and exhibited for half an hour at a time on several occasions a rhythmical flexion and extension of his right forearm. During the night he had incontinence of feces and urine. On the next morning the patient was still unconscious but was not so rigid; his tendon reflexes were not exaggerated, but he still exhibited conjugate deviation of his eyes to the right. He did not begin to answer questions until forty hours after his being cut down, and then he did so stupidly, inaccurately, and slowly. His eyes were now normal and he had regained control of his excreta. He gradually got more lucid and was discharged from the hospital nine days after the accident. He stated that he remembered nothing of his attempt on his life, and thought that he had walked to the hospital with his wife, whereas he had in reality been brought by the police on a stretcher. Though depressed and at times somewhat troublesome, he suffered from no delusions nor hallucinations. Since his discharge he has been sent to an asylum as insane.

British Medical Journal, June 30, 1906.

Pulmonary Embolism.—G. Walker records a case which recovered. His patient was a woman who on the ninth day after her fourth confinement developed phlegmasia dolens. Some two months later, friction sounds developed at the base of the right lung, and she was removed in an ambulance to a neighboring hospital. She stood the journey well, but four days later she suddenly fell back on her pillow and became cyanotic, while the radial pulse disappeared and the pupils were widely dilated. Under strychnine injections (later ether and digitalis) and amyl nitrite inhalations and oxygen gas, she gradually rallied, but later developed phlegmasia in the other leg and pleurisy on the other side. She eventually recovered full health. Diet during acute period consisted of milk and puddings.

Achondroplasia.—A case of this rare affection is described by G. Rankin and E. C. Mackay, who give several photographs and skiagrams of their patient, a lad of nine years when coming under observation. They note that several writers have described the disease under the designation of congenital rachitis. The prominent differential characteristics of the malady are its congenital origin, an abnormally large vault to the cranium, depression of the root of the nose, prognathism, arrested development of the long bones of the extremities, with exaggeration of their normal curves, beaded ribs and enlargement at the ends of the long bones from diaphyseal and epiphyseal changes, decentralization of the mid-point of the body, which is invariably and persistently above and not below the navel, characteristic appearance of the hands (Marie's main-en-trident), excess of adipose tissue, protuberant abdomen, lordosis, smooth, pliable skin, with abundance of glossy hair in all the ordinary situations, a normal mentality, and finally a tendency to other malformations, especially high-arched palate and inguinal hernia. The only conditions with which the disease is liable to be confounded are rachitis and cretinism. Three types of the disease are distinguished: (1) Chondrodystrophia fetalis hypoplastica, in which the epiphysis is normal in size and consistency; there is inhibition of bone formation and also inhibition of proliferation of cartilage cells. (2) Chondrodystrophia fetalis hyperplastica, in which the epiphysis is definitely enlarged and the consistency is variable; there is inhibition of bone formation and increased proliferation of cartilage cells. (3) Chondrodystrophia fetalis malacica, in which the cartilage is softened; there is inhibition of bone formation and the intercellular substance is gelatinous and very vascular. A bibliography is appended.

Berliner klinische Wochenschrift, June 25, 1906.

Two Cases of Spinal Tumor Cured by Operation.—Oppenheim and Borchardt describe these two cases, the diagnosis being made by the former and the operation performed by the latter. One patient was a woman of thirty-three years, with a meningeal tumor at the level of the seventh cervical segment, and the other was a man of forty-nine years, who presented symptoms leading to the diagnosis of a spinal tumor, probably meningeal, at the level of the fifth dorsal vertebra. In each case the diagnosis was confirmed at the operation, which was followed by the relief of almost all the symptoms presented by both patients. Borchardt, in discussing the operations, says that he prefers to perform laminectomy at one sitting rather than in two stages, as has been recommended by some authors, and he states that in his cases, which are now three in number, he has not

been troubled either by undue hemorrhage or escape of cerebrospinal fluid. He also considers that the osteoplastic method of operating is inferior to simple laminectomy, owing to the more complicated nature of the wound it produces. Patients who have been subjected to this operation undergo several risks which are peculiar to this class of cases. One is that of secondary infection, which is very great, owing to the fact that the patients nearly always suffer from incontinence of urine and feces. The danger of the formation of bed sores is also grave, and finally, cystitis may be a very troublesome complication. The technique of the operation and the growths removed are described and illustrated in detail.

Leukemia without Leukemic Blood.—Ewald describes this anomalous case of anemia, which does not appear to fit into the ordinary category of blood diseases. The patient was a man of thirty-seven years, who died after an illness of about six weeks, of which the most prominent symptoms were emaciation, general prostration, and fever. The examination showed 740,500 erythrocytes, and 800 leucocytes to the cubic millimeter; the differential count was as follows: Polynuclears, 71 per cent.; large lymphocytes, 2 per cent.; small lymphocytes, 21 per cent.; myelocytes, 3 per cent.; transitionals, 3 per cent. At the autopsy there were found enlargement of the spleen, jellylike consistency of the bone marrow, which was pink in color, fatty degeneration and dilatation of the heart, submucous hemorrhages in the kidneys and spleen, consolidation of the left lower lobe, adherent pericarditis with adhesions, and lymphoid infiltration of the liver and kidneys. The pathologist made the diagnosis of leukemia with a question mark, and the author details the arguments for and against this view, leaving the question open.

Münchener medizinische Wochenschrift, July 26, 1906.

The Action of Coffee and Cocoa on Gastric Secretion.—Pincussohn studied this question in dogs that had been subjected to Pawlow's operation, by means of which a small portion of the fundus of the stomach is isolated in such a way that its secretion can be collected through a cannula. Such a dog was given water, milk, coffee, tea, and cocoa in different combinations, in order to determine the effect on the secretion of gastric juice. It was found that coffee produced a very prompt increase in the amount and acidity of the gastric juice secreted, the stimulation being of short duration, however. A malt substitute for coffee exhibited the same property, though to a somewhat less marked degree. Tea had a distinctly inhibiting effect. The action of cocoa appeared to depend largely on the amount of fat contained in it. A sample from which most of the cocoa butter had been removed stimulated gastric secretion to about the same degree as the coffee, but a specimen containing a large proportion of fat caused only a very moderate increase, the effect of the fat being strongly inhibitory.

The Use of Opium in the Laryngeal Stenosis of Children.—Hecht considers that this mode of treatment for laryngeal stenosis in diphtheria, which was advocated by Stern in 1894, has not received the recognition it deserves. In cases in which hoarseness, barking cough, stridor, cyanosis, and retraction of the chest indicate incipient obstruction, the necessity for a subsequent tracheotomy may be averted by the use of opium. The explanation of the action of the drug under these conditions is to be found in the inhibition afforded to the coughing impulse, so that sudden congestion in the affected areas is avoided, and there is lessening of the tendency to edematous swelling of the air passages. This applies, of course, only to cases in which the obstruction is not due to membrane formation; and the treatment is not intended to replace the use of antitoxin, but only to serve as an adjuvant to this.

The Treatment of Tuberculosis with Tuberculin.—Krüger has obtained very satisfactory results in the treatment of tuberculosis by means of the injection of very small doses of the tuberculin preparation called "new tuberculin." His cases were twenty-six in number, and of these all but five were in the early stages. Of these five, three were so much benefited that they have been able to work during the past eighteen months to two years. In two cases no direct improvement followed, one patient died of acute phthisis after having gone through intercurrent attacks of scarlatina and of gonorrheal peritonitis. Another patient has been lost track of, so that of the twenty-one incipient cases, nineteen patients have remained well for from two to three years. The initial dose is 0.002 g. of the remedy, injected every other day, and the amount is rapidly increased until at the end of three or four weeks from 0.1 to 0.5 g. is being given. The injections are then made only once or twice a week, and finally at intervals of one or more weeks several doses of 1.0 g. each are administered. No disagreeable symptoms of any gravity are caused, and the author considers the method well worthy of trial in cases in which sanatorium treatment cannot be carried out.

Deutsche medizinische Wochenschrift, June 28, 1906.

Filtrate Aggressins.—Levy and Fornet say that Bail has stated that the aggressins are formed by bacteria not only in the animal body, but also—though more rarely—outside of the living organism. The authors believe that they have demonstrated the presence of aggressive properties in the sterile filtrate of twenty-four and forty-eight-hour bouillon cultures. They have already shown that the Chamberland filtrate of paratyphoid bacilli by itself is not toxic even in large quantities, but that when introduced together with living bacilli it causes the disease symptoms to be greatly increased in intensity and can make fatal doses that otherwise would not be dangerous. It was found, in dealing with the filtrate of typhoid cultures, that by using the ordinarily harmless dose of filtrate of 2 to 5 c.c. of a twenty-four-hour bouillon culture, the fatal dose of the bacilli was reduced from a tenth of a normal loop to a fiftieth of a loop. The filtrate itself was not toxic even in doses of 20 c.c., and control observations with sterile broth were negative. Experiments with leucocytes also showed that the filtrate contained bodies having properties inhibiting phagocytosis and acting in the same way as the aggressins of exudates.

The Spirochetes in the Organs of Syphilitic Infants.—Schlimpert has been able to discover the *Spirochæta pallida* in a number of organs and tissues of congenitally syphilitic infants where they have not previously been demonstrated. The material was obtained from five infants, two of which had lived. The author reaches the conclusion that the *Spirochæta pallida* is able to penetrate between the cells of intact cylindrical and pavement epithelium, and that all of the secretions and excretions of infants suffering from hereditary syphilis must be regarded as infectious as long as it has not been proven that the *Spirochæta pallida* has no etiological relationship to syphilis. Not only the sputum, the feces, the urine, and contents of the mouth, but also the liquor amnii therefore represent a source of danger to the obstetrician and to all other persons coming in contact with the infants. The tissues in which the author was able for the first time to demonstrate the organism are the stomach, mesentery and mesenteric lymph glands, gall-bladder, biliary duct, the peripheral nerves, the thyroid and thymus glands, the tonsils, the tongue, and the mucous membrane of the cheeks and pharynx.

The Production of Radiographs Giving the Effect of Plasticity.—Lewisohn says that at the last Roentgen Congress radiographs were presented, which excited much interest on account of their plastic effect, but to the surprise of all the exhibitor refused to make known the method of their production. Since then Schellenberg and Albers-Schoenberg have described procedures for obtaining this result, and the author suggests the following simplification of Schellenberg's process. A positive is made from the original negative and the two plates are fastened together with their film sides inward, but displaced laterally to a very slight degree, the exact extent of which must be determined by experiment. On inspecting this combination by transmitted light the effect of plasticity will be produced, but to secure prints it is necessary to make another positive in the enlarging camera, and from this positive to obtain a contact negative in the printing frame, from which negative prints may then be made in the usual way. By using this method the original negative is never in danger. The author considers that while the production of pictures of this sort is an interesting scientific diversion, it does not enhance the diagnostic possibilities of the Roentgen ray, as the effects produced are likely to be very misleading.

Syphilitic Aortitis.—Dieulafoy has had decided success in this affection by the use of daily injections of one centigram of biniodide of mercury in aqueous solution. After six or seven injections a notable improvement was shown in one case, which he describes. The writer says this method is the best with which he is acquainted. The dose may vary according to the case. From ten to twelve injections are made in one series, separated by fifteen days or a month of rest. For some years the writer has not prescribed the iodide of potassium.—*La Presse Médicale,*

Book Reviews.

Nature and Health, a Popular Treatise on the Hygiene of the Person and the Home. By Edward Curtis, A.M., M.D., Emeritus Professor of Materia Medica and Therapeutics, Columbia University, New York. New York: Henry Holt & Co., 1906.

It is a hopeful sign of the tendency of the times that works on popular hygiene multiply apace. Prevention goes ahead of cure, and sweet as are the joys of convalescence, sweeter far is the serenity that accompanies a perfect functioning of all the bodily forces. Books on popular medicine are of doubtful utility, but popular treatises on hygience are, when as well written as the one before us, of service to mankind. To be of service, however, they must be readable—not mere don'ts and dos, nor dry physiological essays so technically phrased as not to be understandable of the people, but real health talks in simple language and with a literary flavor to tempt the reader to turn again and again to the instructive page. Such a book is the one before us. The author is a physician of ripe learning, a fluent writer, a poet, and the possessor of a charming literary style. The book, he says, was written out-of-doors, "committed to paper by the wayside, on knee or on the flat tops of fences." And so it reads—not sketchy or disjointed, but breezy and charged with the ozone of the fields and hills, breathing health and strength and life in every page. It can be read as a story is read, and the reader, in his reading, while tasting the pleasure of communion with the mind of the writer, acquires therewith a knowledge of his casement of clay and how to care for it, which, if he but acts upon it, will give him length of days and happy days.

There are fifteen chapters in the book, entitled: Breathing, Eating, Drinking, Drugging for Delectation, Seeing, Hearing, Clothing, Bathing, Disposing of Waste, Disinfecting, Exercising the Body, Exercising the Mind, Sleeping and Waking, Working and Playing, Living and Dying. Each and every one of these chapters can be read and read again, but the one most needed perhaps is that quaintly styled, "Drugging for Delectation." This treats chiefly of alcohol, tobacco, and tea and coffee—all drugs, none necessary, yet none harmful to the average man when taken in moderation. The author treats of their use in a temperate way, pointing out how they may injure and how they may not. He knows that they will be taken by mankind to the end of time, and, knowing that, he does not inveigh against them, but shows how they may be indulged in without harm. Moderation is the keynote, not only of this chapter, but of the whole book.

The Physiology and Therapeutics of the Harrogate Waters, Baths and Climate Applied to the Treatment of Chronic Disease. By William Bain, M.D., (Durh.), M.R.C.P. (Lond.), and Wilfrid Edgecombe, M.D. (Lond.), F.R.C.S. (Eng.), London: Longmans, Green & Co., 1905.

Bain and Edgecombe present far more in this volume than the title shows, for they have written actually a treatise on mineral waters, baths, and climate with special reference to these remedial agents as they are offered at Harrogate, the famous English spa. The book is thoroughly modern in so far as the pharmacology of mineral waters is concerned, and the action of mineral solutions is discussed from the viewpoint of the modern theory of ionization, electrolysis, osmosis, etc. The scientific basis of climate and of baths is also adequately presented, while the concluding chapters deal with the various chronic diseases in which Harrogate has proved of benefit.

Unconscious Therapeutics; or the Personality of the Physician. By Alfred T. Schofield, M.D., M.R.C.S., Hon. Physician to the Friedenheim Hospital, Author of "The Unconscious Mind," "The Force of Mind," etc. Second edition. Philadelphia: P. Blakiston's Son & Co., 1906.

Psychotherapeutics is a branch of the healing art that has a scanty literature; and unfortunately some of what is published on this subject is of such a nature that it cannot appeal to educated and thoughtful readers. Unconscious therapeutics has been left too much in the hands of the quack and of his confrères. Hence, when a book such as the volume before us, written by a distinguished member of the profession, is presented to the medical practitioner, he should avail himself of the opportunity of reading it. The present volume is scholarly and readable; it is absolutely free from all taint of quackery, and may be said to be as ethical as the United States Pharmacopœia and infinitely more interesting. The topics discussed are: The mind in therapeutics, value and varieties of mental therapeutics, the vis medicatrix naturæ, the personality of the physician, other therapeutical influences, from a patient's point of view, the practice of unconscious therapeutics, the secret of success in practice, the action of unconscious therapeutics, and the study of unconscious therapeutics. Much that is given in these pages is not new in itself, but is presented in a new light; and there are few who will not find a perusal of this volume both instructive and entertaining.

Psychotherapeutische Briefe. Von Prof. H. Oppenheim, Berlin. Berlin: S. Karger, 1906.

Oppenheim's letters to "nervous" patients are full of suggestive points to physicians, as they are to laymen suffering from functional disorders of the nervous system. The style deserves to be imitated, and shows the author's wide experience with human failings, mental and physical.

Affectivität, Suggestibilität, Paranoia. Von E. Bleuler, o. Prof. der Psychiatrie in Zürich, Burghöltzli. Halle: Carl Marhold, 1906.

In this essay Bleuler seeks to define the psychological basis of paranoia. He analyzes emotionality and suggestibility as factors of this form of insanity, and concludes that paranoia has been wrongly regarded as an outcome of an abnormal emotional state. The feeling of mistrust, which has been classed as an emotional process cannot be regarded as such, for it does not come under the classification of either pleasure or pain. All abnormal emotionality in paranoia is an outcome of the delusions suffered by the patient. Nothing is known as yet as to the physical basis of paranoia, and thus we are not justified in regarding it as a separate disease.

Études sur le Traitement des Fractures des Membres. Notes recueillies et mises en ordre par les Docteurs J. Guilloux, L. Eissendeck, J. Fadherbe, A. David, L. Merveille, et Ad. Platel, et revues par le Professeur Fr. Guermonprez. Paris: J. Rousset, 1906.

This ponderous volume contains a collection of essays upon the treatment of fractures of the extremities as practised by F. Guermonprez of Lille. Some of these essays are written by Guermonprez himself, while others are from the pen of one or more of his pupils and collaborators. The particular forms of treatment to which most of these studies are devoted are massage, passive and active movements, gymnastics, mechanotherapy, hydrotherapy, electrotherapy, thermotherapy, etc. An enormous mass of data is here collected in the rather informal manner suggested by the title, and the volume is especially rich in historical and bibliographical data. The history of massage from the ancient Egyptians to the modern Swedes is given, for example in an exhaustive manner, and the same may be said of the history of gymnastics, which is a form of treatment older than Hippocrates.

Although nothing in the title or in the preface indicates this, the book, taken as a whole, is conceived in a polemic spirit,—as a defense against prejudiced critics of Guermonprez and his method. Guermonprez, it appears, is or was a teacher of surgery in the "free" or Catholic Faculty of Medicine of Lille, and the essays bristle with hostile allusions to the narrow-mindedness of the French government, the French universities, and the French medical societies. Illegal practitioners, bone setters, etc., are warmly defended, and their frequent superiority over the insufficiently trained "regulars" emphasized in many places, the argument being that the "regulars" were the last to recognize the value of mechanotherapy and the irrationality of permanent immobilization in fractures. Personal animosities are also ventilated in a number of places—as for example where the editor's controversy with the president of a medical society is given in full, the correspondence occupying a number of closely-printed pages, each writer accusing the other of ignorance and of prevarication, the bone of contention, literally speaking, being a fractured femur which was pronounced to be imperfectly reduced by Fr. Guermonprez. In the historical essays, which by far are the most valuable portions of the book, there is evidence of intense Chauvinism. We are told with much bravado that Déclat, and not Lister, was the introducer of carbolic acid as a surgical antiseptic, and that the Institute medal should have gone to Déclat, who was a maker of a set of proprietary medicines. Much more justified, however, is the patriotic claim that Amedée Bonnet (1838-1858) was the inventor of mechanotherapy, which we are accustomed to regard as the product of Zander's genius. Zander, we are told, was but thirteen years old when Bonnet described his first apparatus for mechanotherapy, in 1848. One of the most interesting of the polemics considered in detail is that famous struggle between the Ankylophiles and Ankylophobes, which raged in France in 1870-1880.

As a collection of data on the treatment of fractures the present volume will undoubtedly prove of great value to students of this subject, but the spirit in which it is conceived is far too personal to make the book a serviceable one for general reference.

Society Reports.

NATIONAL ASSOCIATION FOR THE STUDY AND PREVENTION OF TUBERCULOSIS.

Second Annual Meeting, Held in Washington, D. C., May 16, 17, and 18, 1906.

(Special Report to the MEDICAL RECORD.)

GENERAL SESSION.

Thursday, May 17.

Duties, Responsibilities, and Opportunities of the National Association for the Study and Prevention of Tuberculosis.—Dr. LAWRENCE F. FLICK, Philadelphia, Vice-President, delivered an address on this subject. He outlined the fearful ravages of tuberculosis in this country, and said in regard to the work of the Association that great movements always had their beginning in a humble way; these humble movements became united and finally the world was engaged in a great crusade, and he believed the extermination of the great white plague was the world work of this generation. The secret had already been discovered by which this greatest enemy of mankind could be overcome; it had been presented to the world without compensation or return, and it but remained to take advantage of it. He said the great calamaties that had befallen the country from time to time, as the Chicago fire, the Johnstown flood, and the San Francisco earthquake had brought the world to its feet with offerings of assistance, and yet all these calamities combined were not so great as was the calamity of tuberculosis in our country every year; the loss of life in a single year from tuberculosis was fifty times greater than it was in all those calamities; the amount of suffering from tuberculosis for a single year was greater than was the total suffering in those calamities. He believed if the disastrous influence of tuberculosis upon any community was presented to the public in a concrete form in the manner in which the San Francisco earthquake was presented; if all the consumptives could be marshalled together and their suffering presented at a glance, the response for the amelioration of that suffering would be as great as we had just seen in California. He advocated the establishment of hospitals, sanatoria, convalescent farms, and public dispensaries where the poor could be treated. He deprecated the fact that the medical schools turned out so many physicians unacquainted with the best methods of combating the disease and hoped for improvement along this line. He recommended that the Association establish permanent headquarters in Washington and that its invitations to the associations of other countries should have the seal of the approval of the President of the United States Government. He also advocated the establishment of a Lecture Bureau, providing speakers to visit every part of the country and disseminate knowledge of how best to combat the disease.

Friday, May 18.

CLINICAL AND CLIMATOLOGICAL SECTION

DR. VINCENT Y. BOWDITCH OF BOSTON IN THE CHAIR.

The Scope and Aim of the State Sanatorium for Tuberculosis.—Dr. VINCENT Y. BOWDITCH of Boston, Chairman, delivered this address. He referred to the origin of the State sanatorium, and said that to Dr. Trudeau belonged the credit for having been the first in this country to demonstrate what could be done in the treatment of tuberculosis in the sanatorium. The chief idea was to secure absolutely fresh air all the time, and within the last decade these ideas had taken a great hold upon the people throughout the country. He believed that sanatoria should be built away from cities and maintained for the use of incipient cases; advanced cases should not be sent to such institutions, but rather to hospitals in the towns. Sanatoria for patients still in vigorous bodily health should not, he said, be so large as to render individual care impossible, for if proper supervision of the individual was diminished the chances of benefit were lessened. He thought we should aim to make the State sanatoria centers of scientific research.

Report of the Committee on Clinical Nomenclature.—Drs. V. Y. Bowditch of Boston, Lawrason Brown of Saranac Lake, W. H. Bergtold of Denver, Herbert Maxon King of Liberty, George W. Norris of Philadelphia, and John H. Pryor of Buffalo, constituting the Committee, made this report of which Turban's plan, which had already been adopted by the International Association in Europe, was the basis, the committee making some modifications and additions. The plan was unanimously adopted.

Therapeutic Use of Tuberculin Combined with Sanatorium Treatment of Tuberculosis.—Dr. EDWARD L. TRUDEAU of Saranac Lake read this paper. He said the wild enthusiasm that had at first greeted Koch's announcement in regard to tuberculin had soon been followed by denunciation of the proposed method of treatment. It came to be considered dangerous, but he had used it in a limited number of cases continuously since 1890 and he gave a summary of his results in these cases. His conclusion was that tuberculin should be used only in exceptional cases. On the other hand, as a method of revealing the presence of the disease, it was of great value. In spite of the outcry against it, it was based upon a proper idea. It produced no immunity that was lasting; that had only been done by the use of the attenuated bacilli. It had been impossible to reach any conclusion as to the relative value of the different tuberculins; the best was made from the most virulent germ and from the uncrushed bacilli. Dr. Trudeau said we were just on the border of a great field of research, and it remained as yet to be studied out. His method of administration was by minute and gradually increasing doses. If there was marked reaction the intervals between injections were lengthened or the doses diminished. He said in conclusion that he considered the work of Wright and Douglas on the "opsonic index" a most valuable contribution to the knowledge on the subject, but the technique required made it impracticable in treating a large number of cases.

Dr. LAWRASON BROWN of Saranac Lake said he believed that we were at the present time on the verge of a great revival of the tuberculin treatment, but all should constantly observe great moderation in expression and great care in dosage. Above all we should not forget the individualization of each patient, with careful attention to his personal susceptibility. His experience had led him to believe that in many patients there came a time of increased susceptibility when the patients reacted more readily even to doses which previously caused no reaction. Great care had to be exercised until this period was passed. In 70 patients treated with tuberculin no reaction occurred during the whole course of the treatment in 12; 1 reaction in 15; 2 in 13; 3 in 10; 4 in 7; and 5 to 11 reactions in 13. In other words, 50 per cent. of these 70 had 3 or less reactions during the course of their treatment until large doses were reached (over 100 mg. of the old tuberculin, or over 1 mg. of the emulsion).

Dr. E. R. BALDWIN of Saranac Lake thought Dr. Brown had well expressed the present status of tuberculin in saying that it was still in the experimental stage. There were certain things about the reaction that we could not yet be satisfied with; we did not yet know the limits of the reactions or how to explain them. Consequently he thought the use of tuberculin clinically was, as Dr. Brown had said, empirical. He explained that he did not mean by that that it should be limited entirely to people with laboratory experience necessarily, but that it evidently required a great deal of care in its administration. He said the essence of the treatment was the local reaction and the interpretation of that reaction was of prime importance. The local reaction, he said, was a congestion, and the explanation of this congestion was difficult. For himself, he thought it best explained on the enzyme theory, the secretion of some kind

of ferment that digested the toxins, or tended to digest them into simpler forms.

Dr. Arnold C. Klebs of Chicago said that in Europe they had begun using tuberculin to a very great extent again, and it was astonishing to realize how little it had been used here. He had been impressed with the point made by Dr. Trudeau as to the great caution necessary in its employment. Only a few years ago doses had been used that one would not think of employing now. We could not be certain of what was going on and it was difficult to control the effect of the injections. In some cases, he said, there had been no indication at all of a local reaction and he had thought that in such cases harm had been done. He had also been impressed with the fact that the various tuberculins were so very different in their reaction, and furthermore that the effect of the same tuberculin differed in one bottle from another, and he desired to give a word of warning as to the caution that was to be exercised in switching from one kind to another; this he thought was especially true of the emulsion preparations.

Dr. L. Rosenberg of Bedford Station, N. Y., said his results with the use of tuberculin during the past year had been about the same as those of Dr. Trudeau. He thought there had been some improvement in the results obtained, especially in the advanced cases; the best results had been obtained in the moderately advanced cases. He was somewhat skeptical as to the use of the test as a diagnosis of tuberculosis of the lungs, and thought the reaction only indicated that somewhere in the body there was tuberculosis, without showing that it was in the lungs. He employed only the old tuberculin, in vials, and made his own dilution from that.

Dr. S. von Ruck of Asheville, N. C., had been working with an extract of the bacilli themselves, and had found that the agglutinins increased during treatment often 300 to 400 per cent. When the patients failed to come up in nutrition and the progress was unsatisfactory it was noticed that the agglutinins failed to increase. While no hard-and-fast conclusions could be drawn concerning the value of this indication, he felt that they were working along a promising line.

Dr. M. P. Ravenel of Philadelphia said that in regard to the agglutinin test Landis and himself had carried out some experiments along this line and had concluded that it was not delicate enough to be of value. He did not think Dr. Baldwin's theory as to the cause of the reaction a plausible one, as the healing of the lesions was rather in the nature of a fibrosis. In regard to the use of tuberculin in general he said the whole question came back to that of the bacillus; we did not know the toxins of that bacillus; with exactly the same media, grown in the same incubator, they would differ. This might have been due, he thought, to the use of a little more acid or alkali in washing the flasks, as the bacillus was very susceptible to these things. He thought all the preparations would differ, bottle from bottle, because there was no method of standardizing them.

Hematological Studies in Tuberculosis.—Dr. Arnold C. Klebs of Chicago read this paper, which was a detailed technical study of the blood in cases examined and treated in the Cooks County Hospital.

Review of the Work Upon the "Opsonic Index" (Wright and Douglas) in Tuberculosis.—Dr. Nathaniel Bowditch Potter of New York read this paper.

The Treatment of Tuberculous Laryngitis with the Watery Extract of Tubercle Bacilli, with Remarks upon the Action of Specific Medication in the Treatment of Tuberculosis.—Dr. F. M. Pottenger of Los Angeles, Cal., read this paper. He said that this disease rarely occurred unless the lungs were affected, and its diagnosis was a matter of experience and skill in laryngology. The prognosis had always been considered grave, especially by the laryngologists. The writer reported in detail the treatment of fifteen cases, and made a plea for the routine examination of the larynx in all cases of pulmonary tuberculosis. Indications in treatment were, first, to increase the resisting power; second, to prevent spread; third, to heal the local lesion. He thought that as a remedy inoculation was the best. His experience with the tuberculin made from the bovine bacilli had been promising. He had used for the most part the watery extract of the tubercle bacilli, and one thing it did was to keep the condition from spreading. He considered the larynx an ideal location for the use of tuberculin, because the reaction could be watched daily.

Dr. S. von Ruck of Asheville, N. C., called attention to the difference between tuberculin and the watery extract of the tubercle bacillus, the latter being a watery extract of a protoplasmic substance obtained from the bacillus without the application of heat. He said that since he had been making routine examinations of the larynx he had found a much greater percentage of lesions than formerly. With the use of the extract he had found that these showed local reactions, which were never severe and which subsided in a short time, ordinarily without having produced any subjective symptoms. He thought if laryngologists would recognize these facts more generally they would be able to make a greater number of early diagnoses. He had resorted to operative procedure in only 1 per cent. of cases, and that for relief of dyspnea caused by obstruction in the glottis by infiltration.

Use and Abuse of Pulmonary Gymnastics.—Dr. Charles L. Minor of Asheville read this paper.

Dr. Edward O. Otis of Boston said that what was needed along this line was a series of observations and comparisons made upon patients representing as nearly as possible the same general and local conditions. At the Massachusetts State Sanatorium for Tuberculosis such a series of observations had been made. Thirty-seven patients in the quiescent stage of the disease, with no fever, who had been gaining in weight, had more or less cough and bacillary sputum in nearly every instance, were taken in periods of two weeks each. In the first period they were told to refrain from deep breathing, and in the second period they were encouraged to breathe deeply, and four times a day to practise forced respiration. The periods were too short to permit anything but a very general inference. In no case was any ill effect observed during the deep breathing period, nor was the favorable course of the disease prejudiced. The exacerbations occurred during the shallow breathing period, probably only a coincidence. All expressed themselves as feeling better while practising deep breathing. Dr. Crane reported the results in forty-three cases, in which class gymnastics were given for a much longer time and then omitted for some months. No material difference in the condition of the patients or the progress of the disease was observed during the two periods, but the patients generally described themselves as feeling better and eating better during the exercise period. In these cases no ill results were noted.

Dr. Norman Bridge of Los Angeles, Cal., emphasized the fact that pulmonary gymnastics should be administered and prescribed with great caution in pulmonary tuberculosis, and with care that certain and numerous conditions were excluded in which harm might be done. Exercises should be had which would not raise the temperature of the patient, and it was especially desirable that those patients who were below par should have exercise so far as was possible. Much harm was done by fads in breathing exercises and the exploitation of the notion that we had been breathing wrong throughout all ages. When a patient was exercising he would invariably breathe correctly.

Dr. Herbert Maxon King of Liberty, N. Y., said that formerly he carried out systematically the three sets of gymnastics as advocated by Dr. Knopf; but after two years' experience in sanatorium work, he confessed that he could not find that results were of value; could not say positively that pulmonary gymnastics did any harm,

nor could he say that they did good. He preferred to be on the safe side and advised rest for his patients.

Dr. F. I. Knight of Boston said that years ago he allowed his tuberculous patients, during the early stages, to take a great deal of respiratory exercise and deep breathing, but he gradually gave up this practice, for he believed the patients did as well without that exercise as with it.

Dr. John H. Pryor of Buffalo said that it made a great deal of difference whether the subjects were in the incipient or advanced stages. At the New York State Hospital for Incipient Tuberculosis, a form of gymnastics and deep breathing had been carried out since its opening; the patients were given these deep breathing exercises twice a day and no evil results had followed in a single instance. When these patients were sent home they were not soft and flabby, but were in good condition and able at once to go to work.

Dr. S. A. Knopf of New York believed that breathing exercises were both a prophylactic and therapeutic means of value. If the patients were much depressed, let them take breathing exercises and more blood would be furnished the brain, the anemia there would be lessened, and the patients become more cheerful. These exercises were taught the patients at the hospital on North Brother's Island, the forcibly detained cases, old chronic cases, and many of them alcoholics; all looked forward to the time for breathing exercises. So far he had never seen any ill effects.

Dr. Veto of Boston said that a source of error in this discussion was that no distinction was made between pulmonary gymnastics complicated and uncomplicated by general exercises. Even standing or sitting was a general exercise. Therefore an exact pulmonary exercise should be confined to expansion of the lungs in the supine position, with the body entirely at rest. The second source of error was the psychic one; autosuggestion in a community would be of value not only in tuberculosis, but in other conditions of impaired health.

Diet in Tuberculosis.—Dr. Herbert Maxon King of Liberty read this paper. (See page 88.)

Statistics of Diet in Sanatoria for Consumptives.—Dr. Irving Fisher of New Haven read this paper. He presented statistics of diet obtained from institutions in this country and abroad, and in which every possible article of diet could be found. There were 65 tabulations, and in 28 of these institutions forced feeding was approved. The various diets ranged from 2,100 to 5,500 calories, making a very wide range. Dr. Fisher thought that about 3,000 calories should be sufficient for the tuberculous patient.

Dr. Fisher also demonstrated a new method of indicating food values, practically a review of what had appeared in the *American Journal of Physiology* for April 2, 1906.

Dr. Henry P. Loomis of New York said that he agreed with Dr. King that "the diet question in tuberculosis was certainly more than a question of calories, and it could not be decided merely by arriving at the theoretical standard of the amount and relation of proteid fats and carbohydrates." The kind of feeding that would accomplish results in one individual would absolutely fail in another with apparently the same pulmonary involvement and constitutional traits. Since he had adopted the plan of treating all acute cases of tuberculosis with high temperature and markedly destructive lesions exactly as he should a case of typhoid fever with feeding milk almost exclusively every two hours, and often small doses of whiskey in the milk, he had been surprised how quickly the character of the case changed. Milk was the one food that could be absorbed without disturbance under these conditions. It was his belief that we would encounter very few cases of phthisis which were not benefited at some period of their course by the discreet administration of alcohol. It was in the third stage that alcohol appeared to do the most good when taken in small quantities and repeated at regular intervals.

The importance of facts was evident. Cod liver oil was most easily assimilated. In many persons cream produced dyspeptic symptoms, which might be obviated by taking it with a little maraschino, or chartreuse, or mixed with aërated water. He thought that milk, meat, and fat were the most valuable articles of diet we had in treating tuberculosis at home. He did not think that consumptives in our large cities could take raw eggs in large quantities for any length of time without causing digestive disturbances. The plan seemed to be successful with patients living an outdoor life. He gave the following general rules in feeding: 1. Food should be taken at least six times in twenty-four hours; light repasts between the meals and on tiring. 2. One should never eat when suffering from bodily or mental fatigue or nervous excitement. 3. A nap should be taken, or the patient should at least lie down for twenty minutes before the midday and evening meals. 4. Only a small amount of fluid should be taken with the meals. 5. The starches and sugars should be avoided, as also indigestible articles of diet. 6. As far as possible each meal should consist of articles requiring about the same time to digest. 7. Only as much should be eaten as could be easily and fully digested in the time allowed. 8. As long as possible systematic exercise should be taken; when this was impossible massage or passive exercise should be given. 9. The food should be made inviting in every way.

Dr. John W. Brannan of New York said that Dr. Knopf had requested him to give the diet used at Sea Breeze. This was as follows: Breakfast: boiled rice with milk and sugar, two helpings; minced beef with potatoes, one or two helpings; bread and butter, two to four, or even five slices; one or two glasses of milk. Dinner: Stew made from fresh beef and lamb, with carrots, onions, and tomatoes; mashed potatoes; bread and butter, two or three slices; milk, one or two glasses; tapioca pudding. Supper: One egg; buttered toast, two to five slices; stewed peaches; milk as at breakfast. In addition the children had a light luncheon at 10 o'clock and at 3 consisting of bread and butter or crackers and milk. The fact that these children were out doors so much gave them good appetites. The children weighed from thirty to forty pounds, and this gave them about 125 calories per kilo, which was far above what was considered essential in the sanatorium. No alcohol was given, though in France and England beer was allowed.

Dr. Sherman G. Bonney of Denver wished to call attention to the dangers of patients selecting their food without the supervision of a physician. He had found that the average period of delay following the recognition of the disease and the time of arrival in Colorado was about twenty and one-half months. He found that 70 per cent. of these cases arrived with trouble in both lungs, and 54 per cent. had evidences of severe constitutional disturbances, presenting all the evidences of severe septic infection. His first proposition was that the patient should take an extraordinary amount of food daily, all that it was possible to administer within the limits of digestion and assimilation—not what the patient desired or was willing to take, but all that the physician and nurse were able to persuade him to ingest. The tastes, desires, and inclinations of the patient should be considered in the manner of cooking and serving food. Digestive disturbances should be recognized and obviated. The degree of success often depended upon the personal influence of the nurse. A systematic endeavor was made to determine the limit of tolerance for each individual to compel him at any cost to consume the full quantity of food. It had been his practice to administer from two to four ounces of beef juice immediately upon awakening in the morning. This was repeated in the middle of the forenoon, afternoon, and evening, and constituted the only nourishment permitted between meals. He had found that large amounts of food in the shape of raw eggs and cream taken between meals

destroyed the subsequent appetite to a certain extent. This might be obviated by taking the eggs and cream immediately after a meal. Such nourishment could not be taken as a substitute for even a portion of the regular food. It was surprising how many raw eggs an invalid could swallow, even after having taken all the food that seemed possible. Following the eggs a half glass of cream was taken. Emulsions of easily digested fats were often taken a half hour after each meal. In desperate cases nutritive enemata, consisting of beef juice, a beaten egg, and peptonized milk were resorted to. Alcohol was permitted sparingly.

Dr. Irving Fisher of New Haven said he should like to see a trial made of leaving patients to their own devices, after ridding them of the many food notions.

A Suggestion on the Treatment of Hemoptysis.—Dr. Lawrason Brown of Saranac Lake read this paper. His experiments were made upon patients with hemoptysis, taking the blood pressure every two hours, amyl nitrate being used, and morphine for the nervous symptoms. Hemoptysis occurred during the early morning hours as a rule. Dilatation of the peripheral blood-vessels occurred during sleep. In order to equalize the blood pressure sodium nitrate was administered. He hoped that others would try this method to establish its value or to prove its worthlessness.

Manifestations of Syphilis in Connection with Tuberculosis.—Dr. John H. Pryor of Buffalo read this paper. (See page 93.)

Dr. F. I. Knight of Boston said that what he had seen of this combination made him believe that the manifestations of syphilis were not aggravated to any marked degree by tuberculosis, nor were those of tuberculosis aggravated to any marked degree by syphilis. In either case the course might be a long one. The differential diagnosis between tuberculosis and syphilis, particularly of the upper air passages and larynx, was quite easy.

Dr. Dunham said that at Rutland, Mass., they had quite a number of cases in which the two diseases were associated. He had seen a case recently of an ulcer of the tongue, both syphilis and tuberculosis being present. The ulceration cleared up under the administration of the iodides. Patients in whom syphilis was associated with tuberculosis were separated and kept apart from the others.

Dr. Pryor said the diagnosis had been made by the lesions having a different appearance from those of tuberculosis. His idea was that his paper should be largely suggestive. Recently there had been an attempt on the part of some to claim that the two diseases did not exist together. One disease might retard the progress of the other; but exactly what influence one disease had upon the other he did not know.

The Relative Value of Home Treatment of Tuberculosis.—Dr. Lawrence F. Flick of Philadelphia read this paper. He said that by home treatment of tuberculosis he meant treatment of the disease in the home country of the patient, in the climate in which the disease was contracted. It might be in a hotel, boarding-house, sanatorium, or home of the patient. Autopsy records in different parts of the world showed that under the most conservative interpretation 50 per cent. of all people born get an implantation of tuberculosis. As the percentage of people dying from tuberculosis varied from 10 to 25 it was evident that the difference in percentage represented those who either recovered or died from some other disease. In order to recover, the tuberculous subject must eat well, digest well, oxidize well, eliminate well, and sleep well. Whatever interfered with any of these functions inhibited recovery. Homesickness interfered with some, if not all, of these functions for a shorter or longer period. Besides homesickness we had to reckon with fatigue of travel, life in a boarding-house or hotel, and the difficulties of acclimatization as interferences with normal physiological action. Expense was also an item which needed to be carefully weighed in the treatment of tuberculosis, as it might be the ultimate determining factor in recovery. Formerly health resorts had a number of physicians who themselves had gone through an experience with tuberculosis and were able to give better advice than those who had had no such experience. There was in those times no scientific treatment of tuberculosis. Now, with definite knowledge based upon scientific principles, knowledge of the treatment could be given to anyone who had the intelligence to receive it and was willing to acquire it, and men might be as well equipped to treat the disease in the home as in the resort. In many ways the home physician, at least in large cities, might be better equipped because he had better opportunities for qualifying himself to make an early diagnosis, and successful treatment depended much upon early diagnosis. He unhesitatingly affirmed that the modern treatment of tuberculosis could be efficiently administered, irrespective of climate. Men from all parts of the world who had had experience in home treatment of tuberculosis were unanimous upon this subject. A most striking illustration of the value of scientific treatment and complete control as compared with climatic influence had been brought out by the successful treatment of some cases at Phipps Institute which had failed at the White Haven Sanatorium, although the two institutions were under the same medical directors and the same medical staff. The only difference in the medical administration was that one was in the city, where the visiting physician had absolute control and where the most arbitrary discipline was in vogue, while at the institution the visiting physician went only once in two weeks and greater latitude was given the patients. He said that he had no desire to prejudice health resorts or to belittle what had been done by men in those places. When expert services could not be had it was undoubtedly better to go to a health resort than to remain at home.

Dr. S. A. Knopf of New York said he would formulate the maxims which had guided him in directing patients what climate to choose in order to hasten cure. (1) To deny the beneficial influence of certain climatic regions in the treatment of tuberculosis was as dangerous and unscientific as the belief in the specific curative quality of any particular climate. (2) A change of climate, not necessarily a marked one, was nearly always good excepting in the very latter stages of the disease. A change from an unfavorable to a favorable climate, or from a good to a better one was preferable, though when a patient had contracted tuberculosis in a favorable climate a change to even a less favorable one might accomplish much good. (3) The native locality of the tuberculous patient should be taken into consideration in making a change. Those from northern climates usually did better in such climates as Colorado, the Adirondacks, Sullivan and Orange counties of New York. Patients from Italy and our Americans from warmer zones did better in such climates as southern California, New Mexico, Arizona, South Carolina, Virginia, etc. (4) There were exceptions to this rule, and one should be guided in a large measure by the patient's personal experience. (5) Idiosyncrasies existed in regard to climatic and aerotherapeutic treatment as they existed in other forms of therapeutics; these idiosyncrasies could only be learned by experience. (6) High (above 3,000 feet), moderately high (1,500-3,000), and low altitudes, hot and cold regions, seacoast, and ocean climates, extreme dryness and moisture had all proven advantageous in numbers of cases. (7) The value of any climate could not be determined unless the patient lived under careful medical guidance in a sanatorium or private home and followed the best hygienic and dietetic treatment. (8) Laryngeal cases in the earlier stages were often benefited by a moderately high altitude; a weak or diseased heart offered a contraindication to a high altitude. Early hemorrhage need not be considered in determining the choice of climate. In these cases long journeys should be made with frequent rests and high altitudes approached gradually. Cases with bronchial symptoms, weak hearts, and evidences of mixed

infection did well at the seacoast for the greater part of the year. Prolonged ocean voyages might be beneficial under favorable circumstances and where there was no seasickness. (9) The ideal climate was one where the extremes of temperature were not great, with the purest atmosphere, relatively little humidity, much sunshine, and all conditions which permitted the patient to live comfortably out of doors. For tuberculosis of the bones and joints the seacoast climates in our temperate zones came nearer deserving the term "specific" than anything else. (10) In the choice of a locality the following points should be taken into account. These were: (*a*) If the patient wished to return home or not; when great climatic changes had been made a return often resulted in relapse. (*b*) If the patient was married or single, young or old, willing or unwilling to leave; mental depression retarded recovery and aggravated pathological conditions. (*c*) If the patient was sanguine and cheerful, he usually did well even at a long distance from home. (*d*) For the morose and hypochondriac patient isolation often produced the same result as nostalgia. (*e*) It was cruel to remove a patient in an advanced and evidently hopeless stage from his home; slight climatic changes with short distances to travel were often beneficial in such cases. (*f*) The patient's financial condition had to be considered. (11) When the home climate had to be chosen we should take into consideration the following: The patient would do better in the outskirts of a city than in the city, better in the higher parts of the locality, better in a clear or relatively clear and dustless atmosphere, better in a pure or smokeless locality than in one having smoke and odors, better where there were few houses and few people than where there were many. (12) The majority of consumptives were recruited from the laboring classes, and we should have to consider where they would have to live after their restoration to health.

Dr. Sherman G. Bonney of Denver, Col., thought it fortunate that the authors of the papers on climate had been residents of climates usually regarded as unfavorable. He congratulated Dr. Flick upon the results that he had obtained, although greatly handicapped by climatic conditions.

Dr. C. F. McGahan of Aiken, S. C., said that he had been in health resorts all of his professional life, and it was rare to meet with more homesickness than was ordinarily encountered. Freedom from the cares of home usually did much good. At the health resorts there were usually a large percentage of bad cases. The cases were usually kept at home until they were bad, and that was the reason why so large a percentage of cases did not recover at the health resorts. Dr. McGahan said that at Aiken they had had thirty clear days last March. That enabled the tuberculous patients to be out of doors for thirty days of that month, a thing impossible to do in Northern climates at that time of the year. Any patient who went to a health resort should be under medical advice. Patients often fared worse at health resorts than at home, because they were free from home restraints, and were not told to do thus and so. The patient should be told not only how much to eat but how far to walk.

Dr. T. D. Coleman of Augusta, Ga., said there were two distinct types of cases to be considered in this discussion. First, the pauper patients, many of whom live a life of dissipation. If one took them and fed them up and made them live regular hygienic lives, it was evident they were going to gain. Secondly, those who had been accustomed to have better things, and their mode of life was not radically changed by a simple change of climate. He had always considered tuberculosis like any other infection; the ravages it produced depended upon the virulence and amount of infection and the resistance of the patient. If one had tuberculosis and the means to go to a more favorable climate one would not go to New York, Philadelphia, or Chicago and expect to be benefited.

Dr. Thomas Darlington, Health Commissioner of New York City, said there was probably more in climate than many people realized. The New York Board of Health had given this consideration in dealing with the poor class of patients. If one could get fresh air and rest without change of climate one could get wonderful results. This did not mean that we should not add climate. The place where one could get more and better sunshiny days, away from the noisy city, away from the east winds, etc., was what we wanted, and it did make a difference. The poorer class of patients would improve and grow quite stout almost anywhere if they had plenty of food.

Dr. F. I. Knight of Boston said that in his own practice either in the sanatorium or at home he never made a suggestion of change of climate unless the patient was able to afford it. He thought that patients who submitted to the proper treatment at home were more likely to be depressed than those away from home. They were fearfully depressed if they had ahead of them a second winter of outdoor treatment in New England. Some of his patients had returned home and had not done well, but he doubted if any such patient had ever recovered when remaining in the home climate. All were agreed on the subject of not sending away advanced cases.

What May be Accomplished in Apparently Hopeless Cases of Pulmonary Tuberculosis.—Dr. Sherman G. Bonney of Denver read this paper.

SECTION ON DISEASES OF CHILDREN.

Second Day—Wednesday, June 6.

The Use of Sodium Citrate as a Modifier of Cow's Milk from a Chemical and Physical Point of View.—Dr. Joseph W. England of Philadelphia read this paper referring to the first recommendation by Wright in 1893 of sodium citrate for the treatment of proteid-indigestion and the vomiting of chronic gastric catarrh. The writer had made a series of experiments with milk and various reagents, and presented a score or more of specimens of different combinations. His conclusions were expressed in the opinion that sodium citrate, which was a neutral salt, had no decomposing action upon calcium casein in the cold, but that it did exert an important physical influence upon the casein of milk; that when the citrated milk was brought in contact with the gastric juice, the sodium citrate was decomposed into sodium chloride and free citric acid, and that sodium chloride had important physical, chemical, and therapeutic properties, in the digestion of the proteids of cow's milk, more important probably than had been hitherto believed.

Diagnosis of Tuberculosis in Infants and Children.—Dr. Edward E. Graham of Philadelphia, in a paper with this title, stated that about 8 per cent. of all children who died showed at autopsy evidences of tuberculosis; that tuberculosis was common in children over four months of age; that congenital tuberculosis was rare, and that of the number of cases reported of children who died of tuberculosis before the fourth month many were probably congenital. In probably 90 per cent. of cases infection took place through the respiratory tract. Dr. Graham described a chronic, a subacute, and an acute form of pulmonary tuberculosis in infancy and childhood. The difficulties in making a positive diagnosis of tuberculosis were also pointed out. The possibility of infection should be considered and the hygienic surroundings. Inoculation experiments of glandular substance were often of aid in a differential diagnosis, and in the more chronic types of the disease might decide the tuberculous nature of the illness. In a doubtful case presenting skin eruptions the tubercle bacillus, he said, had been recovered from the

eruption as in a case recently reported by Dr. Irving Snow of Buffalo. Examination of the fluid removed by lumbar puncture he considered of aid in diagnosis. Tuberculin he had used very little; the presence of an irregular fever frequently seen in young children, in his opinion, rendered its use of doubtful value in many cases. Leucocytosis was usually absent unless there was mixed infection. The occurrence of digestive leucocytosis must be taken into consideration in this connection. Blood cultures were often of value in differentiating tuberculosis from pneumonia or typhoid fever by showing the presence of the pneumococcus or the typhoid bacillus. Chlorosis was mentioned as often presenting a picture resembling closely tuberculosis of the lungs and lymphatics. Dr. Graham did not wish to imply that the diagnosis of tuberculosis was as a rule difficult in the advanced stages; but in those cases in which the symptoms were vague and indefinite the diagnosis was often obscure. In such cases the writer was often asked to decide upon the presence or absence of tuberculosis and it was hoped that the discussion would throw light upon this differential diagnosis.

Dr. Arthur W. Fairbanks of Boston referred to a point in the differential diagnosis of typhoid fever and tuberculosis in the adult which he thought applied also to the child, *i.e.* the difference in the relation between the pulse and temperature in the two diseases. In tuberculosis the pulse was disproportionately rapid as compared with the temperature; with the temperature running from 100° to 101° the pulse would be 125 to 150 in the adult. This was still more the case in the child. In typhoid conditions exactly the opposite was true. Dr. Morse had also told him of his observation of this occurrence in a large number of cases in children.

Dr. C. G. Kerley of New York suggested that in the presence of a long indefinite temperature sometimes seen in children, if the child had had measles, that the ear be regarded as possibly the source of the temperature. Particularly in young children he had seen cases in which there was no symptom whatever of an otitis or mastoiditis other than a low indefinite fever.

Dr. T. J. Elteritch of Pittsburg said that in the Allegheny General Hospital in children suffering from any acute or chronic disease the ears were carefully examined by an expert, and that a surprisingly large number of children were found suffering from middle-ear infection, the diagnosis having been previously made of typhoid fever or other infectious conditions before entering the hospital.

Dr. William J. Butler of Chicago observed that the post-mortem diagnosis of tuberculosis in an infant did not necessarily indicate that the child had died of tuberculosis, such infants being far more likely to be the victims of a bronchopneumonia. He did not think that the relation of the temperature and pulse rate could be relied upon in the differential diagnosis of typhoid fever and tubeculosis or of bronchopneumonia, since it was a matter of general observation that the pulse rate and temperature in children did not conform to rules applying to the adult. Particularly confusing in the diagnosis of tuberculosis in infants was the decided disproportion between the clinical manifestations and the pulmonary signs; too frequently in advanced tuberculosis in infants and very young children the former were of a severe character and the local pulmonary findings consisted of a few dry râles.

The Open-Air Treatment of Pneumonia.—Dr. W. P. Northrup of New York read this paper. He said that for more than eleven years he had been treating pneumonia patients in cool, fresh air, gradually placing their beds nearer and nearer the open window. Last winter he put them out on the roof. His remarks upon the beneficial effects of open-air treatment were founded mainly upon last year's experience at the Presbyterian Hospital, where it was the systematic practice in all of the winter months to put all pneumonia cases for six hours of the day on the roof in the open air, in all weather except high, harsh winds, rain or snow. Some protection was provided against little rains and snowfalls. The plan of treatment had not been adopted without much observation and some self-education. Dr. Northrup did not underestimate drugs, but magnified the therapeutic value of hygienic measures, especially water and fresh air, believing that the two most important aids were plenty of water, inside and outside, and fresh air everywhere. The theory was illustrated with the case of a girl of three years admitted with lobar pneumonia. Measles was suspected and the child was temporarily isolated in a small room with a screen about the bed. The fever immediately rose, the child became delirious and dusky in the face, but upon being taken to the roof it fell into a quiet sleep. The cases most favorably affected by the open-air treatment were those with severe poisoning, delirium, partial cyanosis, or deep stupor. No cases of pneumonia had been injured and a few had been much aided. He had employed the treatment for many other infectious diseases including typhoid fever with severe bronchitis, whooping-cough with bronchitis and convulsions, and the results had been excellent. The only regulation was to make the patients comfortable, especially keeping their feet warm. The Presbyterian Hospital was so convinced of the value of the treatment for all infectious fevers that it had built a roof garden for the children's ward and was about to build a colossal roof garden on the main roof of the medical side of the hospital. In this open-air ward the fever patients would be kept so long as their fever was high. In good weather they occupied the open part of the ward; in bad weather they were moved into the more sheltered part.

Dr. Edwin E. Graham of Philadelphia narrated his experience in the open-air treatment in hospital service of 40 or 50 children under one year of age. He began by putting them out on the fire escape, bundled in blankets and the cribs covered with towels. Later he had dispensed with the towels over the cribs, having the children well blanketed and their heads covered with very warm caps. The results had been surprisingly gratifying.

An Analysis of Forty Cases of Meningitis in Infancy.—Dr. John Lovett Morse of Boston in this paper referred to his study of 20 cases of tuberculous and 20 cases of cerebrospinal meningitis at the Infants' Hospital. The diagnosis was made in every case either by autopsy or lumbar puncture. The onset was not infrequently sudden in the tuberculous cases and was often slow in the cerebrospinal. There was nothing characteristic about the temperature in either class. A slow pulse was unusual in both classes. The pulse was often irregular in both and there was always a terminal rise. A low respiratory rate was also very unusual. Stupor was common throughout the greater part of the disease in both types. Vomiting was very common in the cerebrospinal form. Constipation was present in about one-third of each class. Convulsions occurred in less than half of each class. Neck symptoms were rather more common in the cerebrospinal cases. Spasm and paralysis were not at all constant symptoms. Kernig's sign was often absent throughout the whole of the disease and was usually inconstant. Eye symptoms were not at all constant. The fontanelle bulged in most cases; it was level throughout the whole course of the disease in four of the tuberculous and in two of the cerebrospinal cases. The abdomen was usually sunken and muscular spasm was almost always absent. An eruption occurred in only one of the cerebrospinal cases. The duration was less than two weeks in twelve cases of the tuberculous form. Dr. Morse's conclusions were that the picture of meningitis in infancy was materially different from that of meningitis in childhood and from that given in most textbooks. The tuberculous form had a more sudden onset and a shorter course than in later life. The symptomatology of the tuberculous and cerebrospinal forms was essentially the same at this age, although the symptoms of spinal, and, to a less extent, of cerebral irritation, were, on the whole, more marked in the cerebrospinal. These differences, however, are insufficient to justify a differential diagnosis. The history or presence of a reasonable cause

for the tuberculous form pointed strongly to this disease, but such evidence was frequently entirely wanting. A positive diagnosis between the two forms was impossible on the symptomatology and could be made only by an examination of the cerebrospinal fluid obtained by lumbar puncture. Lumbar puncture, he stated, had no curative value in cerebrospinal meningitis, but was very useful for the relief of symptoms in both forms.

Dr. Arthur Fairbanks of Boston referred to two cases of tuberculous meningitis; to one, on account of the peculiar character of the onset; the other, because of the peculiar post-mortem condition. The onset in the first case, that of a girl of six years, was characterized by attacks of uncontrollable disobedience in a previously docile disposition. Temperature was about 101°. She resisted all attempts at examination until within eight days of her death when all resistance ceased. The second case had been admitted to the hospital because of otitis. Ataxia subsequently developed; dullness came over the child; the pulse dropped suddenly and the temperature steadily rose. Post-mortem examination showed the entire surface of the cerebellum covered with tubercles and section of the vermiform process revealed complete caseation.

Cerebral Syphilis in Children.—Dr. Arthur W. Fairbanks of Boston read this paper, which was based in part upon the study of somewhat over 100 cases of undoubted syphilitic cerebral disease in children from the literature. That the subject is deserving of a special chapter in pediatrics is evinced by the large number of instances of the affection to be found in the literature and by its unquestionable relation to other and very common affections in childhood not usually regarded as of septic nature. The onset of the phenomena produced by syphilitic lesions of the central nervous structure was multiform. The onset was, as a rule, subacute with the occasional occurrence of individual symptoms of very acute character and severe degree, the latter phenomena being characterized by their tendency to disappear after brief duration and to recur in some other portion of the body. Reference was made to the rapidity with which some cases yielded to treatment, while the reverse was true in others. The symptoms varied in character and degree, but at some one time some one class of symptoms rendered themselves conspicuous by special predominance. By a consideration of the nature of onset, progress and duration of the predominant phenomena some inference might be drawn as to the probable pathological type present in any given case. Changes in disposition and intellect were noted as frequent early symptoms in children; not always apparent in the history obtained from parents, however. While some symptoms might seem to occur without premonition, careful scrutiny of the child's life would reveal early evidence in insidious changes in the psychical nature of the child. Other symptoms mentioned were circulatory disorders—vertigo, disturbance of speech and vision and syncopal attacks. The diagnosis was considered in detail, as was also the prognosis.

Multiple Neuromata of the Skin.—Dr. William Edgar Darnall of Atlantic City read this paper, presenting three cases of this uncommon affection. The tumor was described as presenting itself in the form of multiple hard, spindle-shaped masses, varying from the size of a small pea to that of a walnut, distributed along the course of a single nerve, of all the nerves of an extremity, or even of the whole body. Originating from the connective tissue of the nerve sheaths the tumor usually contained within its substance a certain number of nerve fibres included by the tumor in the course of its development. Quotations were given from the various reports of cases. A case occurring in the author's own practice was described, as were two others, notes of which had been sent him by Dr. William G. Spiller of Philadelphia and by Dr. Harry A. Duncan, Pathologist to the Samaritan Hospital of Philadelphia.

HEALTH OF SCHOOL CHILDREN.*

A STATEMENT OF THE ENDEAVORS OF THE BOARD OF EDUCATION TO CONSERVE THE HEALTH OF CHILDREN UNDER ITS CARE.

By LUTHER HALSEY GULICK, M.D.,

NEW YORK.

DIRECTOR OF PHYSICAL TRAINING, NEW YORK PUBLIC SCHOOLS.

When one speaks of the schools of New York City, visions of great buildings containing thousands of children, situated in the congested parts of the city, come to mind. Public School 188, Manhattan, down on the lower East Side, has on its register 4,363 pupils. Public School 84, Brooklyn, has on its register 4,805 pupils. These enormous schools, embracing numbers equivalent to the population of a fair-sized village community, form, however, only one phase of the picture Public School 121, Brooklyn, last winter had on its register 36 pupils. The total number of principals, instructors, assistants, and the like was—one. Public School 7, Richmond, had 26 pupils on its roll; and in place of the 66 class-rooms in Public School 84, Brooklyn, it contained but one room, thus corresponding exactly to those village school buildings that have become so well known in the history of this country.

In discussing the health of school children we are then discussing an enormously varied group of problems—those of the single-room building in a sparsely settled territory, where the children live a considerable distance from the school; and at the same time those of the great compact building situated in the most congested districts of the world, with narrow streets, high adjoining buildings, amid a population having the most varied national characteristics.

Ventilation.—There has been appointed upon the Building Committee, which has charge of the erecting and the equipment of all new buildings, a duly qualified medical man, Dr. Louis Haupt, thus insuring to this committee that expert counsel which is needed in all such work.

All school buildings now being erected are being ventilated by the so-called "plenum" system. The air is forced into the room and finds its way out through special vents leading to the roof. Special hoods are installed to assist the flow and to prevent back draughts. The air is taken into the building at the level of the first or second stories, is carried through ducts to the cellar, there passes through a blower, and is carried into the class-room. It enters the class-room near the ceiling and is dispersed through all parts of the room by deflectors, finds its way finally to a vent near the floor, and is forced out by the incoming air. The system is planned on the basis of furnishing 30 cubic feet of air to each pupil per minute, the basis of calculation being 50 pupils to a room. Each room contains an average of 9,000 cubic feet, or 180 cubic feet per pupil.

In view of the fact that there has been considerable criticism, not with reference to the theory of this plenum system, but with reference to the efficiency with which it was administered in the New York public schools, Dr. C. Ward Crampton, Assistant Director of Physical Training, in cooperation with the Building Department, recently made a series of tests of 23 rooms in different buildings. I quote below part of Dr. Crampton's report. These rooms were selected, part of them in a direction toward the wind, part away from the wind; and in other respects as well the conditions sought were as varied as possible. I shall not burden you with a detailed report, but it was with great satisfaction that we discovered that the average income of air for these 23 rooms was 1,584 cubic feet per minute. This was not estimate, but careful measurement. "The air in the rooms, with but few exceptions, was rapidly changed in six or seven minutes. In those rooms where the air change was not complete, it was due to corners in which the air seemed to stagnate. This was the only evidence of failure in this system of ventilation. No pupils were seated in these corners."

Heating.—"In the plenum system the air strikes first a series of steam pipes, known as 'tempering coils,' which are only in use when the temperature of the outside air is below 40°. These coils bring the air to this temperature. The air is then passed through two series of steam coils. The upper one is set at 70°, the lower one at 68°. When the temperature of the air in the duct entering the class-room falls below 70°, the steam is automatically turned into the upper coil. Should it continue to fall below 68°, the steam is also turned into the lower coil. This is accomplished automatically by thermostats."

Purity of Air.—"The Department of Buildings is now installing an entirely new feature which will insure not only purity of air, but the proper amount of humidity as well. There is to be placed in one of the new buildings an air washer or purifier. The air passes a tempering coil and is drawn through a chamber in which it is thoroughly saturated with water from spray jets. It is next passed through a series of baffle plates which reduces the water and leaves the air at the 50 per cent. humidity mark. The surfaces of these plates catch all the excess moisture, and with it are deposited all particles of dust and impurities. The air then passes through the heating system and is distributed through the building. This is a great advance, as it insures the cleanliness of the air supplied to the class-room. It appears to me that this system of ventilation now in use is most

*Read before the New York Academy of Medicine on May 24, 1906.

highly efficient in that it unquestionably furnishes each child with the requisite amount of pure air."

Accommodations.—That there should be over 70,000 children who can be only partially accommodated in the schools in their vicinity seems in itself to be a condemnation of the Board of Education, particularly in view of the fact that this condition has now obtained with greater or lesser severity for a number of years. The reasons back of these conditions are not primarily financial, as they are supposed to be, but they are administrative. For example, last year there moved out of the lower East Side of Manhattan 50,000 persons who went over to Brooklyn and settled in what is known as Brownsville. The school population of Brownsville at that time was 14,221. It was immediately increased by 3,123—22 per cent. in one year. This was one of the most seriously congested districts in the city before the flood of immigration came. It had at that time 6,323 pupils on "part time." The increase raised the number on "part time" to 11,031 and increased the school population to 17,344. If this immigration had come to a district less seriously burdened, it would not have been so difficult to meet. The school accommodation, which was already inadequate, was overwhelmed. Extensive plans were already under way to remedy the congestion. These have been extended and hastened. Five buildings, which will accommodate 10,150 children, are now under way. Six thousand sittings would give each child a seat; but the Board are so sure of the continued growth of this district that they have not only allowed a leeway of 4,000, but have already had recommended by the Sites Committee three additional buildings.

It usually takes three years after the need for increased school facilities has been demonstrated to discover the proper site, to have this site approved, the property condemned, plans drawn and approved, and the building erected. The difficulty is not that the city is growing faster than it is possible to plan ahead for it, but that it is growing in unexpected ways, in unexpected places, and at unexpected times. There are now approximately enough sittings in Greater New York to accommodate all the children, but the location of the sittings does not correspond with the location of the children. A building with 1,000 seats cannot accommodate 1,000 children without ignoring their individual needs by dividing them into ten groups of exactly fifty each.

Lighting.—The standard size of rooms being placed in new buildings is 30 x 22 x 14 feet. The principle of unilateral lighting is regularly adopted, except in corner rooms. The so-called "H" building permits of the location of the school in the middle of a block and affords to every room adequate light and area. This is a type of building which I understand was developed by Mr. Snyder, the Superintendent of Buildings. The amount of window space is never less than 20 per cent. of the floor area, nor more than 25 per cent. The top of the window is 13 feet 6 inches from the floor. The distance across the room is never over 22 feet, which is less than twice the height.

Vision.—However perfectly the school building may be ventilated, with what degree of perfection light may be regulated and admitted, temperature controlled, humidity adjusted, the desk perfectly fitted to the individual, periods of sitting still shortened, and periods of varied bodily and manual activity lengthened—the central difficulty of school life remains. It is a difficulty which is dependent upon the fact that the treasures of civilization are stored in print—in minute black marks upon a white surface, which must be held relatively close to the eyes. This involves a conscious attention and strain of the ocular apparatus to which it was not adapted during the long ages when it was being developed. Even under the most favorable conditions, the strain of civilization rests most heavily upon the child with reference not merely to the eye, but also to the nerve centers back of the eyes, and to that very great symptom-complex which is associated, as we have only recently discovered, with eyestrain.

Examinations made in many cities and those made in New York under the direction of the Board of Health, have satisfied us that not less than 30 per cent. of all children in our elementary schools are suffering from ocular defects demanding correction, and not less than 17 per cent. have ocular defects so severe as to be a serious menace to their progress. These defects acquire their significance, not because they are defects merely, but because they are defects of that portion of the human organism upon which learning and education largely rest. The relation of this condition to school work is shown by the fact that ocular defects are in direct ratio to the length of time the pupil has attended school. This is the point of strain, this is the point that demands more aggressive and constant safeguarding than any other of the systems of apparatus that we each possess.

For diagnosis and treatment the Board of Education must depend upon the Board of Health. All that the Board of Education can do is to secure adequate lighting and suitable print, to prevent long consecutive use of short focus work, and to get the children to hold the book at a fair distance and at a right angle.

Seating.—The largest sedentary class in the civilized world is probably that of public school children. The significance of this fact is fully realized when we remember that the ordinary effects of sedentary occupation are accentuated, because the individuals are growing rapidly. Hence the interference is not merely with function, but with growth as well. The effects of badly-fitting school desks accentuate the manifest evils of sitting still. A desk which is too high, too low, or too far from the pupil may easily be the indirect agent for causing scoliosis, producing or aggravating myopia or astigmatism, interfering with the development of the legs through pressure upon the popliteal arteries, and the development of automatisms in the unconscious effort of the child to relieve the strained positions.

There are two ways in which the Board of Education aims to combat the evils that are incident to sitting at school desks. The first of these is by minimizing the length of time that the child shall sit still, and the second by having a school desk as nearly related to the child who is to sit in it as is feasible. Every child in the elementary schools is required, at least twice in the morning and once in the afternoon, to take the so-called "setting-up exercise." This exercise secures a large excursion of the diaphragm, thus accelerating abdominal circulation, increasing respiration and circulation in the arterial and venous system generally by the contraction of the large muscular masses of the back and legs. It also most forcibly extends the spine, calling attention to those parts of it which are bent forward chiefly in the sitting position, namely, the dorsal and cervical portions.

The modern school differs from the school of a

generation ago in no respect more markedly than with reference to its relation to the activity of the child. It seemed to be the earlier practice to regard the children as so many vessels that were to be filled with knowledge. The present situation is more accurately represented by the statement that the children are regarded as individuals, who have powers that are to be developed by specific activities of various kinds; and that these specific activities involve not merely action of the intellectual powers, but that they involve the activities of the hands, of the body, and of the vocal organs as well. The result is that instead of sitting still five hours per day, there is relatively little sitting still. A rather careful inquiry among the schools would indicate that in the lower grades less than 50 per cent. of the time is spent in sitting still, and that only in the last grades is more than three-fifths of the time spent in relatively motionless position. I think, then, it is clear that if children do not sit still for any long, consecutive period and for not more than two hours out of the five, and that during the day they take exercises specifically designed to counteract the effect of a predominately sedentary occupation—the problem is not as grave as it would be under the conditions of five hours of sitting still which obtained in the schools of a generation ago.

With reference to the adaptation of the desk to the child there are very important things to be said. The Board of Education, after careful investigation, has selected forms of adjustable school seats and desks, in order to give to children that which shall be best related to their needs. As a matter of fact, however, after the preliminary adjustment, these seats are rarely altered, for the following reasons:

Pupils in high schools have no permanent seats, but go from room to room as they change subjects. Thus each pupil during the day will occupy four or five different seats. It is obvious that under such conditions it is neither necessary nor possible to have the seats adjusted to the individual pupil. All that can be done is to have the general grading of seats correspond to the general grading of the schools, and then to seat the tall children in the back of the room and the short children in the front. There is, however, in this administration, one obvious and thus far, unsolved difficulty. Children who are myopic or who are deaf in one or both ears, should be seated so that the disability will interfere with the progress as little as possible. If the case chances to be one of the tall pupils and the indications point to his being seated where the seats are low, the difficulty is real.

With reference to the elementary schools it must be explained that in the upper two years a large number of schools is organized on the so-called "departmental" basis, which means that the pupils go from room to room in pursuing the different subjects, exactly as pupils do in the high schools. The conditions that have just been described for the high schools apply, therefore, equally to these elementary schools organized on the departmental basis. This organization is proceeding rapidly and bids fair to become general.

Beginning now with the lowest grades in the kindergarten, we find small, solid chairs, which are designed to be moved into any part of the room where they are needed. These chairs are used by different pupils and at tables rather than at desks, as the floor must be cleared for the games that occupy such a large fraction of time in the kindergarten.

In the classes above the kindergarten and below the departmental grades, we find the following fact: In 70,000 cases the pupil is able to come to school but part of the day. This is because of congestion. These are the so-called "part time" classes. Two pupils each day occupy the same desk. The only adjustment possible in such cases is the general one and of having in each room such an assortment of such sizes of furniture as will suit the average class. The classes are promoted twice each year, but the changes of individual children from room to room and from school to school are so great as to constitute a serious difficulty in the way of adjustment of school furniture to the individual, even in those schools where there are no "part time" classes.

The adjustment of the seat and desk to the individual pupil involves the following measurements of the child: Height of knee, in order that the seat may be adjusted; and height of elbow when the child is properly seated, for the adjustment of the desk. If the desk is adjustable front and back, as it should be, an additional measurement is needed in order to adjust the desk to the proper distance. I have indicated merely the most fundamental measurements.

To secure these measurements for the 600,000 children of New York City schools is at the present time impossible. In our large schools are from 1,000 to 5,000 pupils. The adjustment of each desk to fit in several respects the measurements of these numbers of children presents a problem in administration which has not been solved. It would involve the special employment of a considerable force of persons. I believe the time will come when with the cooperation of the Board of Health it will be possible to do far better than is now being done in the adjustment of furniture to the individual; but in view of the conditions of relatively brief sitting periods and many periods of muscular activity, I believe that there are other and more pressing problems with reference to school health than that of the adjustment of school furniture.

Scoliosis.—Recognizing that the constant carrying of a weight on one side of the body is one of the predisposing causes toward scoliosis, particularly in girls of weak musculature, I had the weights of books carried home by children examined in a large number of schools. The facts with reference to the seventh year, dealing with girls approximately thirteen years of age, may be taken as a fair sample. From observations made of this class in forty-five schools it was found that the number of books carried on the average was 4.7, and that the average weight was 5 1-8 pounds. The books were carried on the left arm by 69 per cent. of the pupils. The reasons for carrying books about are: first, some of the books are needed for home study; secondly, as many of the schools are used in the evenings by other pupils, the desks must be left empty; thirdly, and very prominently, the pride of many girls who like to go on the streets with a large number of books so as to appear to be in a high grade. One report noted a child who had carried twenty-one blank pads to swell the total. It is our endeavor, which endeavor is being furthered by a large number of principals and teachers, to induce the children to carry these books alternately on the right and on the left arm.

It should also be noted in this connection that the chief aim of physical training in the schools is

to secure a good posture and particularly vigor of the muscles that support the spine and hold it erect. We have thus eliminated pretty largely muscular weakness and habitually bad posture as factors in the direction of scoliosis in the children of the New York City public schools.

Over-Study.—In view of the normal activity of children, there is no danger, so far as school work is concerned, that they will do work involving too great activity. The danger is that the work will be too one-sided intellectually. If we analyze the school work for the first year, we discover that out of the total 25 hours per week, which are available between nine in the morning and three in the afternoon on the five school days, 1¼ hours are given to opening exercises, 7½ hours are given to physical training, talks on cleanliness, and the like, games and recesses, 1 2-3 hours to penmanship, 1½ hours to nature study, 2 hours to drawing and constructive work, ½ hour to weaving with cord and raffia, 1 hour to sewing. A total of 15 hours and 25 minutes, or 62 per cent. of all the time, is thus given to work which is nearly all of it such as to involve muscular activity, none of it involving study. It is needless to say that no home work is demanded of these little children. The total amount of time per week given to English is 7½ hours, and to mathematics 2 hours and 5 minutes, making a total of 9 hours and 35 minutes per week, or a little under two hours per day. Two hours per day judiciously interspersed with recesses, games, gymnastics, hand work, drawing, and music, is not an excessive burden.

Turning now to the fourth year, during which the children are about ten years of age, we find 1¼ hours given to opening exercises, 2¼ hours to physical training, recesses and organized games; 1¼ hours to penmanship, 1½ hours to nature study, 2 hours to drawing and constructive work, 1 hour to sewing, 1 hour to music, making a total of 10¼ hours, 0 41 per cent. The Board of Superintendents recommends to parents that the children be not allowed to study over an hour per day outside of school on this work. Thus we have, during the day four hours spent on intellectual tasks, broken up into short periods by physical training, manual training, music, recesses, and with less than one hour of home study. This does not seem to me to be either in theory or in practice excessive.

With reference to the eighth year, where the pressure is said to be the worst, we find 1¼ hours spent in opening exercises, 1¼ hours in physical training or games, 1 hour and 20 minutes given to drawing and constructive work, 1 hour to music, 1 hour and 20 minutes of science work, which is, to a considerable extent, done with apparatus, so that it should be classed with the more organic subjects. This gives a total of 6 hours per week. It leaves 3 hours and 48 minutes per day given to intellectual tasks. No period is longer than 40 minutes. The amount of home study is by request of the Superintendent of Schools to be limited to an hour and a half per day.

In view of these facts, how are we to account for the other facts that children are frequently overworked and that the number of nervous and fatigued children is considerable? There are several other factors in the case. I have not discussed the problem of overwork in the high schools, because they include such a small factor of the total number of pupils. I believe, however, that the conditions in the high schools are not as favorable with reference to overwork as they are in the elementary schools. It is unfair to charge up to the Department of Education all the evils that result from very short nights, after-school work of an economic character, malnutrition, and the effects of tenement housing.

1. It is true that many children are nervous and ambitious to a far greater extent than are other children, and that the amount of pressure which it is necessary to bring to bear upon average children to secure from them normal and reasonable work, tends to produce overexertion on the part of the more sensitive ones. This will account for the strenuous life of many ambitious girls and a few boys.

2. There is a considerable number of cases where overwork is to be accounted for on the ground of excessive expenditure of energy in other directions than that of school life. There are many children who have not yet reached adolescence whose hours of sleep are totally uncontrolled, who are usually out late in the evening. Upon such children the burden of school life does rest too heavily, because they do not have the needed recuperation.

3. A most unfortunate class consists of those who are obliged to work either early or late to help toward their own support or that of the family.

The present course of study is adapted neither to the very bright nor to the exceedingly slow. It is inevitable, therefore, that the bright shall find it at times tending to mind wandering, because it is too easy; and the exceedingly slow shall find it pressing upon them with undue severity. For these reasons it has been made increasingly easy for children to "skip" grades. The complete remedy for both of these cases would be to have so few children in each class that there could be a very high degree of personal acquaintance and individual treatment. The difficulties in the way of this will be discussed in another section.

Malnutrition.—We must all agree that it is fundamental to the welfare of the state that children shall be well-nourished during the growing period. There is little of any value in the world, in any permanent way, unless children grow up healthy and vigorous. Our science, art, literature, and religion will not only sink into relative obscurity, but they have in themselves no possible good except upon the basis of the life of those which they are to serve. With this general truth (which no doubt will be differently stated by different people) we must all agree.

But in a rapidly-developing state, a state in which every decade presents problems which are both fundamental and new, there exist inevitably, confusion and lack of agreement with reference to that particular arm of the State which shall look to and provide for the various needs of the community. The Department of Education has developed gradually, out of the needs of pauper children. It is no longer a charity but is patronized by the great majority of our citizens. The Board of Health arose out of the need of corporate action with reference to the spread of contagious diseases.

Many children in this community are underfed. Many more are badly fed, with equally injurious results. Does this problem belong to the Board of Health or to the Board of Education? It is a matter that relates to health and yet education is fruitless except upon the basis of good nutrition. The British Parliament is apparently about to authorize the supplying of meals to young children—a plan that has already been adopted in Paris and a number of other European cities. This is one of the problems that has not been attacked by either the Board of Health or by the Board of Education

in New York City. It is nevertheless a fundamental one—and I believe, a prominent one—so long as poverty and ignorance shall continue. It demands solution. The solution may be carried out by the Board of Education, but ultimately it is a medical question—not an educational question. The authoritative word and public opinion both are to be made through the medical men of this city. I believe the time will come when all school children will be offered an adequate lunch, furnished by the Board of Education. There must needs be, however, a large amount of public education before this can be accomplished.

Feeble-Minded Children.—During the past few years it has slowly developed in this city, as in other cities, that there is a small percentage of children—from one-half of one to two per cent.—so below grade mentally as to be incapable of the most profitable education in classes with average children. It is further recognized that one of the fundamental difficulties with reference to these unfortunates in many cases is malnutrition. Accordingly, the Board of Education has employed a specialist, Dr. Elias G. Brown, who spends his whole time in examining those whom principals and teachers think may be in such condition as to profit most by the special classes provided for these cases. He advises with reference to the care of such children and counsels with reference to their condition. This is recognized to be but a first step in a much larger plan. The success of treating these children in special classes, by methods in which manual work, physical work, baths, and the like are made prominent, has been such as to warrant extension of the work to include other classes of cases.

Defective Children.—The Board of Education last winter, on the recommendation of the Superintendent of Schools, Dr. William H. Maxwell, has taken up the consideration of care for the blind, the deaf, and those who are crippled. It is not too much to say that provision in special classes and special institutions will be made for these cases as rapidly as is possible. Hasty movement, however, in the face of so complex a set of problems is, of course, impossible. Each special class must be approached tentatively and methods of work best adapted to a public school system under American conditions must be slowly elaborated.

Physical Training.—The amount of time that can be spent for physical training in the different grades is as follows (time schedule on the basis of 1,500 minutes per week):

Years	I	II	III	IV	V	VI	VII	VIII	
	450	165	165	150	90	90	90	90	minutes

During these comparatively few moments it is obviously impossible to attempt even to give each pupil that general physical exercise which all children need. That is, it is not possible during the school day to undertake that general physical training which belongs to the playground, to the athletic field, or to the home. Neither is it possible, in this brief time, to give the pupil all the recreation that is needed. The first and most important aim of our school gymnastics is to counteract the effect of the school desk.

The partially flexed spinal column allowing the sternum to approximate closer to the vertebræ than normal, which allows the muscular layers of the abdominal wall, as well as the supporting members of the abdominal viscera to relax, results in a train of evils which is perfectly familiar to all since the classic work of Glenard, "Le Ptosis General." A decreased portal circulation, lessened intestinal peristalsis, a lower blood pressure, a shallower breathing—a familiar symptom-complex—these symptoms are more marked in a growing child than in adults whose muscles and bones have already acquired full development. It is not wise to give exercises that shall induce perspiration, for change of clothing is not possible and the child must continue in his school work immediately after the exercises. Nor is it possible to give exercises that shall involve a large amount of noise. In the great majority of cases the pupils must take their exercises in the class-room. Eighty-three of the five hundred buildings possess gymnasiums, which renders the problem somewhat easier.

The first and most direct means taken to meet these conditions is what we call our "Two Minute Exercise." In it there is emphasis upon forced deep breathing, with its effect upon portal circulation through the influence of the alternate contraction and relaxation of the diaphragm. Vigorous work is given to the extensors of the spine. This is in order to counteract the constant stretching that occurs when one bends the back forward. These exercises also call into play the large muscles surrounding the shoulder and the hip joints, as well as the extensors of the leg. Thus the large muscle masses of the body are exercised, the circulation thereby quickened, and the consumption of oxygen increased. These exercises are given at the end of each hour in the morning and between the two hours in the afternoon. The windows are opened during the exercises. Thus it is that where the system is fully carried out, a pupil never sits two consecutive hours without there intervening this group of exercises.

The second measure which is taken to combat the effects of the school desk, is the formal physical training. This consists of a series of exercises, the chief emphasis of which is placed upon movements of the large muscular masses rather than upon delicate and complicated movements of small muscular groups. The effects sought are primarily physiological. These exercises are not designed to take the place of play, nor to furnish the general exercises that the pupil needs. They are designed to combat the effects of the school desk, to secure to each pupil good carriage, and erect and vigorous habits of walking.

In the schools having gymnasiums it is possible to use the lighter forms of apparatus, such as dumb bells, wands, Indian clubs, and the like. In other schools free exercises only can be used. In both cases there are prescribed and taught by the teachers series of exercises which demand increasing muscular strength, endurance, and control from grade to grade. In addition to these formal gymnastic exercises, it is possible in the lower grades to have a considerable number of vigorous gymnastic games, having for their purpose general recreation and physical training, which in the upper years must be carried on outside of school hours.

With reference now to the after-school activities, in the line of athletics, for our public school boys and girls: This work must, in the nature of the case, be voluntary. It cannot be carried on officially by the Board of Education, for this Board is not related to the out-of-school activities of children. There has, therefore, come into existence a great organization, known as the "Public Schools Athletic League." This League has on its board of directors the President of the Board of Education, the Superintendent of Schools, district superintendents, high and elementary

school principals, class teachers, business men in the community, and others who are especially competent and interested in the problems of athletics for boys and girls.

The first endeavor of this Athletic League was in the direction of establishing great sets of city games of the ordinary kind: running, jumping, relay racing, etc. We clearly understand that these conventional athletics suffice merely to bring into prominence those boys who need athletic training the least; that is, those who are by inheritance and test endowed in physique and stamina.

Fashion and wont are such great elements among boys as well as adults that this seems to be the most useful way of teaching the athletic spirit, cultivating school loyalty, and the like. These great city games constitute the dramatic elements that appear in the public press and which are talked about by the boys. They do not, however, represent the chief work of the League, nor its main interests. Its main interests and its largest activities are to get boys having average or below average attainment, into vigorous athletic sports. The devices that are used for this purpose are, in the nature of the case, experimental and original. I mention but one: it is called "class athletics." We are giving trophies to the class in the borough of a given grade that can run the fastest for a short distance, or that can jump the farthest. Every member of the class is timed in his running or measured in his jumping, and an average is struck. This is compared with the average for other classes. There is much interest in this. The boys who are most expert help the boys who are less expert, because the average is influenced even more by the inferior runners than by the superior ones.

The problem of athletic sports for girls we are just now seriously attacking. There is now a public wave of interest in athletics for girls and women. This interest has already, in many cases, led girls and women to overdo. They have not had preliminary athletic experience, nor are they physiologically competent to wisely undertake athletics of as strenuous a character as those which are provided for boys and men. Our first object, then, is to exercise a controlling influence with reference to these sports, to see that they are not overdone and that unprepared individuals are kept out of them altogether. We aim also to devise new sports and to modify old ones, so that they shall be as adapted to the development of girls as the present forms of athletics are to boys.

The Board of Education is conducting two forms of after-school activity which are closely related to the health of its children. One is known as the Evening Recreation Centers, and the other as the Afternoon and Evening Playgrounds. During the year 1904–1905, in the most congested parts of the city, 21 schools were opened in the evening as recreation centers. In these schools ample opportunities were afforded for games, dancing, gymnastics, as well as the more quiet forms of recreation. The average attendance at these 21 recreation centers was 7,276 per evening. Some of the recreation centers were equipped with shower baths. The average number of persons taking baths per evening was 148. During the summer, after the close of the regular schools, the Board of Education opens a large number of gymnasiums and playgrounds in the afternoon. Last summer there were in operation 67 of such playgrounds. Regular gymnastic work and plays and games of many kinds, under expert supervision, are carried on in this way. The average attendance last year was 38,566 per day. During the evenings 11 of the schools having suitably equipped roofs, opened these roofs to the public, provided bands, and supplied expert supervision. The average attendance at these 11 roofs was 32,148. The 7 schools having bath equipments during last summer gave a total of 288,387 baths. The average per day is not recorded.

Instruction in Physiology and Hygiene.—In passing, mere reference can be made to this subject. It would demand a whole paper to acquaint you with any degree of fairness with the respects in which this work is being done.

Instruction is given as to the effects of alcohol and narcotics, in accordance with the law of the State. In doing this, particular pains are taken to emphasize the constructive phases of the subject—not to elaborate upon pathology or to depict pathological conditions. The case against the general consumption of alcohol is sufficiently great, so that it is found to be wholly unnecessary to resort to any extreme statements in order to carry out the provisions of the law.

A single point of view is taken each year rather than the mere repetition of the subject matter with greater detail year after year. For example, in the fourth year there is the general topic of good health; the fifth year, what children may do in the emergencies in which they may find themselves; the sixth year, health from the standpoint of the dweller in towns, contagious diseases, water supply, and the like. In the seventh year we find the usual physiology and hygiene. In the eighth year the questions of personal habits, personal control, and the like are discussed, as well as to some extent the nervous system and the special senses.

Ideals.—It may not be out of place to indicate some ideals toward which additional progress should be made with reference to the health of school children.

1. There should be individual care, personal inquiry and knowledge of the home life of approximately the lower tenth of every class. This includes those who, for one reason or another, twice fail of promotion. This work is now being done to some extent by the school nurses, under the employ of the Board of Health. The work should be very greatly extended. Allowing that there are but 500,000 children, of which but 50,000 need this individual attention, and that each school nurse can wisely handle 100 such cases, keeping in personal touch with them and with their families, it would take 500 nurses. These 500 nurses would add to the wealth of the State by saving to efficient lives a large fraction of those who now come to adult life with such a degree of impaired vigor or defective development as to be relatively unproductive in an economic sense. Whatever is necessary to be done to prevent incompetence must be done. This can only be accomplished by personal attention of a consecutive character by a person who is qualified from the standpoint of health, in cooperation with a physician.

2. We need to have the consecutive records of all children as to age, height, weight, eye, ear, nose, throat, heart, lungs, and so on. Only in this way can the highest degree of efficiency be secured. I was much interested recently to see in the current press accounts of medical care of certain child laborers in India. This care was given most efficiently, not from the standpoint of humanitarian interests, but because it was discovered that the working capacity of the children was a direct function of their health,

and that it paid financially to keep them well. It will pay well educationally for us to keep track of the children with reference to these matters of health. It is a relative waste of money to endeavor to train the nervous system of a child that is seriously undernourished, whose growth is perverted, and who has reflex irritation from defective teeth, eyes, and so on. This work which is being undertaken in such a vigorous way by the Board of Health, must be extended and coordinated more perfectly with the Board of Education.

3. The size of classes should be decreased, so that the nervous strain upon teachers shall be lessened; so that there shall be opportunity for a larger degree of individual attention than now obtains; so that teachers may be able to become personally acquainted with the children and to some extent have regard for their health in a way that is not possible in classes of fifty or sixty, where each one must be pressed into certain objective standards.

4. London has a minimum requirement of 30 square feet of playground space for each child in connection with the schools. This is very little. New York should do no less, and yet for a large school—for Public School 188, in which there are approximately 5,000 children—it would take 150,000 square feet, or a square of 130 yards on the side. An average city block up-town is 200 feet wide and 600 feet long. It would take a block 50 feet wide and 300 feet long to provide the needed area for this one school.

5. There should be an open-air playground within walking distance of each child. What is walking distance for a child three years old needs to be very near. Places where older boys may play ball need not be so close together.

6. Special classes and schools should be organized for defective children of all kinds. It matters not if these are crippled because of disability of the osseous system, the ocular, the auditory, or from central lack of development. The demands both of humanity and of social economy involve the care of these unfortunates by the public schools.

In making progress such as is here suggested, two fundamental factors are involved: first, an agreement as to what ought to be done; and second, the power to do. Concerning the wisdom of most of these steps the medical and educational men of the world are pretty well agreed, but the power is not yet present. Institutions like the public schools cannot proceed very much in advance of public sentiment, particularly when such advance involves the expenditure of large amounts of money. To furnish 500 school nurses together with such organization, supplies, and the like as they would need, would involve the annual expenditure of upwards of $500,000. To secure the consecutive examination of all children, as is recommended, would involve the employment for the city, I should estimate, of not less than 250 medical examiners. The present property value of the public schools is not less than $150,000,000. To add to this so that each child could be in a class not to exceed thirty children, would involve the expenditure of an additional 60 per cent., or $90,000,000. The additional teaching and supervisory force would cost about $15,000,000 per annum more than the $25,000,000 now spent. To furnish for each school thirty square feet of playground space would cost many more millions; how many it would be difficult to estimate. To furnish a playground within walking distance of each child in the congested districts is not possible on the present basis. If each child below Fourteenth Street were to be given a space three yards square, it would demand that approximately every fifth building should be torn down in that area. The development of many-storied playgrounds seems to me to be inevitable. The development of special classes and schools for all defectives would be an exceedingly large enterprise.

The most serious obstacle in the progress of such a program as I have outlined is the lack of informed public opinion as to the necessity for these things. Our city possesses the money and is inclined to deal very generously with all matters affecting the health and welfare of children. But the parents of most of these children were brought up under conditions of either relatively little school life, or of school life on the old basis of the three "R's" and under conditions where a considerable degree of that general motor education which goes with domestic work and cooperation of boys with the parents was possible. These citizens probably fail to realize that the conditions have changed completely; that it is no longer possible for children in central parts of New York City to play out of doors, as they themselves did, or to secure that muscular training and that motor education in connection with domestic work or cooperation with the fathers in their work which they themselves secured; and further, that these functions must be discharged with reference to the children by the State through the public schools, because under the conditions named the home no longer serves the need of the children in these respects. What we need, then, is education of public opinion.

The most capable body for the formation of opinion with reference to the health of school children and with reference to specific steps that need to be taken in order to wisely meet the conditions of child-life as presented by the city, is the distinguished professional body, members of which I have the privilege of addressing this evening. Progress is being made in every one of the directions that I have named. The Board of Education is not merely interested, but regards the health of school children as fundamental—as more fundamental than education—and recognizes its own responsibility with reference to these things; but under present conditions of public opinion it cannot proceed materially faster than it is now going. Great strides have been made during the last decade. In fact, nearly all that is being done with reference to the health of the children has been developed during this decade. All that has been outlined can be carried out as soon as it is possible to procure the funds. The physicians of this community are in a position to speak authoritatively with reference to these things, as no other persons can speak. They can enable the Board of Education to do these things. Without their help the Board of Education must proceed slowly and lamely in these matters.

During the winter of 1905 there was an extended attack on the Board of Education because it used physical training, manual training, drawing, music, cooking—all those subjects that involve the training of the body, the training of the eye and the hand, the training of the breathing apparatus, the vocal apparatus—all of them involving central coordinations, motor images, and the like. That was a time when the Board of Education needed the support of the medical men of this city. Such support was not given. The Board of Education needs and craves not only the advice, but also and equally the support for every step which it takes

with reference to increasing the health, the personal efficiency, and the power to live of these complex groups of children that come to it from all over the world. For these reasons it was with peculiar pleasure and gratification that I received the kind invitation which has made the presentation of this paper possible.

THE PHYSICAL CARE OF SCHOOL CHILDREN.

By ROWLAND GODFREY FREEMAN, M.D.,

NEW YORK.

LECTURER ON PEDIATRICS, UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL SCHOOL; ATTENDING PHYSICIAN FOUNDLING HOSPITAL AND NURSERY AND CHILD'S HOSPITAL, THE SEASIDE HOSPITAL OF ST. JOHN'S GUILD, NEW YORK.

It is probably the opinion of most physicians of this city who have the care of children that almost all school children are overworked, and that this is true in all grades of school life, in the kindergarten, the primary school, the secondary school; and the same is true of young men in the professional schools. This overworking is a natural tendency, because children are sent to school to learn certain facts and to receive mental training, and each institution is striving for a high standard of scholarship. Such a practice is apt to cause some physical wrecks, as we know is the case in New York, through a straining of the nervous system or on account of the lack of physical exercise caused by continuous application to studies, while indirectly by overworking the teachers who are apt to become neurasthenic, there is set up a reflected nervous irritability in their pupils.

Under good surroundings that can be regulated, the care of children, both by parents and physician, is a source of considerable satisfaction and pleasure until they enter the kindergarten or school. Until that time they may be troubled occasionally with slight colds, with constipation, or with adenoid hypertrophy, but as a rule they may be kept in good health. As soon as the child is entered in the kindergarten infections are more apt to occur. Colds recur more frequently, and the ordinary acute infectious diseases of children are apt to break out. Whooping-cough, mumps, chicken-pox, and measles usually occur within a few years after the entrance at the kindergarten. As the child leaves the kindergarten and enters the primary school this liability to contract contagious diseases persists, while the prolonged concentration required in the school régime produces frequently, toward the end of the school year, certain nervous disorders, of which chorea and hysteria are the more common varieties.

The question naturally arises whether these disadvantages of our present school system are due to any defect in school methods, or whether they are only an accompaniment of a system of education that is necessary for each generation, and whether school life could in any way be modified so as to impart sufficient knowledge without impairing the health of the child, and with less liability of exposing the child to contagious diseases.

Let us first consider what are the essentials of the preservation of good health in children.

First, they need ample rest. They should have ten or twelve hours in bed at night, and often with advantage a nap after the midday meal.

Second. A proper diet: A moderate breakfast, a substantial but digestible dinner, and a simple supper. All these meals to be eaten slowly and well masticated.

Third. Fresh air. A child should be out-of-doors several hours a day, and when in the house should be in rooms well ventilated and provided with at least 1,500 cubic feet of air space per person.

Fourth. Freedom from dust and exposure to disease. Infections due to dust and the direct exposure to contagious diseases cause a large part of the sickness of school children.

Fifth. Freedom from worry and fatigue. Neurasthenia exists in earliest infancy and is common in school children. It is induced by anxiety, and particularly in children by prolonged application. The child can exert itself intensely for short periods without harm, but prolonged application produces marked fatigue.

Our experience tells us that when these five essentials of good health can be maintained—ample rest, proper diet, fresh air, freedom from infection and freedom from worry—there is usually little difficulty in securing prolonged good health. Our problem, then, is to ascertain whether such conditions are practicable for our school children. They are certainly not offered now to any school children. Can private or public schools be organized that would afford them?

The first condition, ample rest, may be obtained with our present school arrangements, except that with most classes no opportunity is allowed for a nap after dinner. This is not necessary in all cases, but is always desirable. The diet is also a matter for home regulation, except in public school children, but this opportunity for the children to take their hearty midday meal at leisure is often prevented by too small an allowance of time for the noonday recess. In some of our best schools but forty-five minutes are allowed for the child to go to his home, eat the most substantial meal of the day with meat, and return to school. One hour would seem to be too little for such a recess. The question whether our public school system should not provide one nourishing meal a day, at least to those children who are poorly fed at home, is a matter that we cannot discuss here, although it is evident that the best work cannot be obtained from the underfed.

When we consider the lack of facilities of obtaining fresh air by our school children, we find one of the most potent elements in the production of disease among them. The defective ventilation of school buildings is in common with all public buildings, and the popular fear of a draught often interferes with a sufficient opening of windows.

In the consideration of outdoor play, it is necessary to separate the private school children from the public school children, and we must also remember that it is not sufficient to give all children an opportunity to get into the fresh air if they will, but that it is necessary to force some children of natural sedentary habits to play out of doors.

Children go to school in the morning, remaining until noon; return at one, remaining until perhaps three, after which some will play in the streets and others return to their homes, having had practically no out-of-door play during the day.

New York has previously offered few facilities for outdoor play for school children. It seems to me that the provision for this outdoor play, which is essential to their health, and thus must be obtained if they are to do good school work, should devolve upon the educational authorities.

This problem may be solved to some extent by the public school, which could keep the children

under supervision during the whole day, having a supervisor of physical exercise remain with them before and after school hours, when they could play in enclosed cages on the roofs or in adjacent public parks under supervision.

The important influence that such supervision would have, not only upon the physical condition but on their moral development, would be worth to the city far more than the expense. Indeed, it would be an economy in diminishing expense for the suppression of crime when these children grow up.

In some of our best private schools provision for play under supervision is made, but such play is too often carried on in closed rooms, and not out of doors, so that a large part of the advantage that might accrue from it is thus lost.

My own feeling is that the time will soon come when our best private schools will move to the suburbs of the city, where, instead of occupying a plot fifty by one hundred, they can have several acres of land. The child could sleep at home, go to the school in the morning, obtain the outdoor play there, and return to his home late in the afternoon. The parents would thus remain in touch with their children in a way not possible at boarding schools, while at the same time the children would enjoy the facilities for outdoor play which are such an advantage to our boarding school children.

The effort to protect school children from disease has brought about many improvements in our public school system, but has not as yet effected many changes in private schools, although some inspection exists in many of the latter. The excluding of sick children has never been as rigidly carried out as it should be to protect those that are well. So far as I know children with colds are excluded from only one private school in New York City, while it is well known that so-called colds are often an evidence of influenza, which is a very contagious disease; that they exist for three days preceding the eruption of measles, while what is known as a cold is the common phenomenen of the first two weeks of whooping-cough before the characteristic cough develops. If children with colds were absolutely excluded from our schools measles epidemics would not travel so fast, whooping-cough would be much less prevalent, and through the diminution of influenza school attendance would be markedly improved.

I was recently called to see a boy suffering from sore throat, who was attending a kindergarten class of eight children. I asked him whether the children had all been in attendance on the preceding day. He said no, that he was the only child there. I visited the school the following day and found no member of the class present, and on inquiry learned that one of the children had come to school with a slight cold the week before. Had that child been excluded it is not likely that the other seven children would have been absent at that time.

Next to colds, the most common evidence of contagious diseases in children may be said to be eruptions; so that no child with an eruption should be allowed at school until the eruption has been pronounced by a competent person as not an indication of a contagious disease. The presence of dust in school rooms is naturally a source of danger, and should be reduced to a minimum by careful and proper cleaning of the floors and furniture.

Fatigue in school children was well demonstrated in a scientific manner by Dr. Christopher of Chicago, who supervised some excellent work on the public school children of that city. By means of the ergograph, which tests motor activity in the middle finger, he examined a number of children in different schools. In each case he found their activity greatest when entering school at nine o'clock; that it diminished rapidly during the morning session, reaching its lowest point at noon, when they were dismissed. At one, after returning, it had reached about the same maximum as at nine in the morning, and during the afternoon it diminished even faster than during the morning. He found the same results in all the children tested, except in one group of four boys in one of the schools, who showed no deterioration in physical activity during the day. On investigating these cases it was found that the teacher of these boys had been absent, and while they had been in school all day they explained that they had been having a good time. It, therefore, appeared that this deterioration in physical activity, when present, was the result of prolonged application, and not of the confinement in school.

The relief of school children from worry and from fatigue from prolonged application can best be secured by shortened school hours, by short periods devoted to any one subject, and frequent recesses devoted to physical exercise. Such a scheme should be so worked out that, when controlled by some instrument such as that used by Dr. Christopher, school work would result in no appreciable deterioration.

Through the kindness of Miss Carse, the principal of the Charlton school, I have tested for fatigue certain children under her care. I chose for the test children who were for the first time undertaking work that required concentration—that is, children of about seven years. I applied the Crampton test for fatigue, the comparison of pulse rapidity and blood pressure, taken standing and lying down, and the test with the ergograph.* The children were tested just after coming to school at nine o'clock and just before leaving at half-past twelve. In none of the children examined was any marked fatigue shown. Most of the tests average as good at twelve thirty as at nine o'clock in the morning. The reason for this striking absence of fatigue may be found in the examination of the daily program. The school day lasts only from nine to twelve-thirty. The session consists of periods of but fifteen minutes devoted to any subject, and each fifteen minutes the children are alternately standing and sitting. The middle of the session is interrupted by a fifteen-minute recess out of doors, and an hour later by a five-minute recess spent in jumping through the seats. These observations of mine are too limited to base large conclusions upon, but the unusual absence of fatigue in most of the children examined would seem to indicate that the program was very successful.

There can be no question but that proper physical development is more important for our school children than any knowledge that can be imparted to them. The acquirement of knowledge accomplished by physical injury is harmful, not beneficial.

*The writer is indebted to Professor F. S. Lee of the College of Physicians and Surgeons, Columbia University, for many valuable suggestions and for the apparatus loaned to him for the experiments.

It is usually the case that when little children of five years, who have previously been kept out of doors all day, and have had no concentration on any subject, enter kindergarten classes, where a session of one hour should be sufficient, you will find two and one-half hours required, during which period not more than twenty-five minutes of recess is allowed. As they grow older, at ten years four hours will be required, with no more recess than the kindergarten child had, and with more time devoted to the preparation of lessons of the following day.

It is my opinion that for children between five and ten years of age not more than ten or fifteen minutes should be devoted to any one subject, and that this period should be followed by five minutes of active exercise in the open air or with the windows open; that but one hour should be devoted to work by children of five years, and that not more than one-half hour should be added each succeeding year up to ten years; and that a part of the school day should be out-of-door play in the afternoon under supervision.

To summarize, then, our ideal private school should be out of town, but within easy reach of the homes of its patrons. It should have short periods of study, separated by frequent recesses, and ample time allowed for a substantial midday meal, taken at leisure. The harder work should be given during the morning hours, the lighter work in the afternoon hours, to be followed by play out of doors, in which all the children must take part.

The ideal public school should take the children as many hours a day as practicable. They should come to school as early as eight in the morning and enjoy an hour's outdoor play under supervision before undertaking their tasks. The periods devoted to each subject should be short, with frequent recesses. At noon a nutritious but simple meal should be furnished them. In the afternoon the easier subjects, the manual work, and the preparation for the lessons of the next day should be taken up. Opportunity for out-of-door exercise under supervision until late in the afternoon should be provided.

In both private and public schools a much more severe examination for any evidence of contagious diseases should be made than at present. All children with colds should be absolutely excluded from school, and children with eruptions should be excluded until the eruption has been pronounced by a competent person noncontagious in character.

205 West Fifty-seventh Street.

TREATMENT OF APPENDICITIS.*

By F. D. GRAY, M.D.,

Jersey City, N. J.

Surgeon to the City, Christ, and North Hudson Hospitals.

In America, at present, the advisability of operation at some stage of appendicitis—or subsequently—is conceded by a large majority of the profession and laity. This same majority agree upon operation in all early cases, barring some strong contraindication. The term "early" is preferable to the measure of a certain number of hours after the onset, and it indicates absence of complications, such as perforation, abscess, local, spreading, or general peritonitis, infection of pelvic organs, or such systemic effects as septicemia, pyemia, pneumonia, etc.

A smaller but increasing proportion of the profession would defer operation, in late cases, where one or more of the above complications exist, until the interval, which they believe will come about by means of preliminary treatment, popularly known as Ochsner's, because Dr. Ochsner of Chicago has more thoroughly and persistently than anyone else, practised and publicly advocated its use. It is consistent also to speak of the Ochsner method as the conservative, contrasted with the radical plan of treatment, wherein immediate operation is done at any stage of the disease, when the diagnosis is clear and the patient not moribund.

Conversation and correspondence with other physicians have convinced me that a more or less hazy idea of Ochsner's concept of conservative treatment of appendicitis exists, some thinking that he decries all operations; others that he operates only during the interval; while not a few are unfamiliar with the details of treatment by which he expects to bring a complicated case to the interval for what he considers a safe operation.

The limits of this paper prevent my presenting Ochsner's argument as fully as I should like. I am therefore compelled to abstract as briefly as possible a paper read by him at Chattanooga, October 14, 1904.

He said in part: "1. The mortality in appendicitis results from the extension of infection from the appendix to the peritoneum, or from metastatic infection from the same source.

"2. This extension can be prevented by removing the appendix while the infectious material is still confined to that organ.

"3. The distribution or extension of the infection is accomplished by the peristaltic action of the small intestines.

"4. It is also accomplished by operation after the infectious material has extended beyond the appendix and before it has become circumscribed.

"5. Peristalsis of the small intestine can be inhibited by prohibiting the use of every form of nourishment and cathartic by mouth and by employing gastric lavage in order to remove any food substances or mucus from the stomach.

"6. In this manner very dangerous cases of acute appendicitis may be changed into relatively harmless cases of chronic appendicitis.

"7. In my personal experience no case of acute appendicitis has died in which absolutely no food of any kind and no cathartics were given by mouth from the beginning of the attack."

These constitute the nucleus of Ochsner's argument. He then makes the following suggestions, based on his arguments for the treatment of appendicitis:

"1. Patients with chronic recurrent appendicitis should be operated on during the interval.

"2. Those with acute appendicitis should be operated on as soon as diagnosis is made, provided . . . the infectious material is still confined to the appendix, if a competent surgeon is available."

(Thus far you notice that he agrees with the radicals), but he says further:

"3. In all cases of acute appendicitis, without regard to the treatment contemplated, the administration of food and cathartics by mouth should be absolutely prohibited, and large enemeta should never be given.

"4. In cases of nausea or vomiting or gaseous

*Read in a Symposium on Appendicitis at the annual meeting of the Medical Society of the State of New Jersey, held at Atlantic City, June 19, 20 and 21, 1906.

distention of the abdomen, gastric lavage should be employed."

(Now especially, he differs from those practising radical methods.)

"5. In cases coming under treatment after the infection has extended beyond the tissues of the appendix, especially in the presence of beginning diffuse peritonitis, conclusions three and four should always be employed until the patient's condition makes operative interference safe.

"6. In case no operation is performed, neither nourishment nor cathartics should be given by mouth until the patient has been free from pain and otherwise normal for at least four days."

Now as to Ochsner's statistics, covering 1,000 consecutive cases, including seven fatal ones that died without operation; they are as follows:

	Cases	*Deaths*	*Death Rate*
Chronic appendicitis or interval operations	540	3	0.5%
Acute appendicitis without perforation	255	5	1.9%
Acute, perforated, or gangrenous without abscess	55	..	.....
Acute, perforated with abscess	117	4	3.4%
Acute appendicitis with diffuse peritonitis	33	10	30.0%
Total	1,000	22	2.2%

This must be conceded as a remarkable showing for 1,000 mixed cases, and yet, in the approximate bearing and value to the general practitioner of medicine and surgery, one must carefully consider the fact that all were operated upon by a surgeon of much more than ordinary ability (with well trained assistants), both in judgment and technique, all in the same hospital and under good surroundings.

A comparison of work under such conditions, with the results by more radical surgeons, who operate not only in one hospital, but perhaps in two or even three, and in houses as well, with different sets of assistants—in many cases not accustomed to their methods of technique, can never be absolutely fair and may be very misleading.

Believing as I do, that the chief issue regarding treatment of appendicitis to-day concerns the line of cleavage between the radical surgeon who would operate immediately upon all complicated cases (not moribund) upon satisfying the diagnosis, and the conservative one who would wait for the subsidence of acute symptoms; in other words, the interval, I concluded to send a list of queries to a considerable number of men—presumably representing both classes.

Through the courtesy of Dr. Ochsner I secured a list of about twenty surgeons, who, he assured me were using his method. Next I selected about an equal number whom I had reason to believe were treating such cases radically and sent to each the following printed form, with stamped envelope for return:

1. Have you ever given the "Ochsner" treatment of complicated appendicitis a thorough trial?
2. If so, in how many cases (exact or approximate)?
3. What has been your mortality rate (exact or approximate)?
4. How have the results compared with your other cases of the same character treated by radical operation?
5. If you have not practised the "Ochsner" method, what, in your judgment, are (briefly) a few of the most important features of the operative treatment of complicated cases, especially in presence of general peritonitis?
6. What has been your operative mortality rate (exact or approximate) in early, uncomplicated appendicitis?
7. The same in complicated cases?

As a result of forty such requests I received eighteen answers about equally distributed between the two divisions. I see no special advantage in mentioning names when I summarize briefly the results of my correspondence, though I do not consider it by any means of a confidential character.

A source of disappointment lay in the fact, on one hand, that among the Ochsnerians (if I may coin the word) such small lists were given as a basis for conclusions—ranging from two to forty-seven. Again a large proportion were unable to give exact statistics. Further, two distinguished surgeons and authors, who presumably use the radical method and could no doubt furnish valuable data, begged to be excused.

The largest number of cases reported treated by the conservative method, as I have said, was forty-seven, the smallest two. The surgeon reporting forty-seven cases said the mortality was practically *nil*, and yet acknowledged two deaths—4.25 per cent. One reported twenty-five cases by the conservative method with ten deaths—40 per cent., while his mortality in complicated cases by radical operation was only 8 per cent.

A report from the Carney Hospital, Boston, said that they had used the Ochsner method "in quite a number of cases," that the mortality in 450 cases during the last two and three-quarter years—all stages and all methods implied—was 3⅓ per cent. This, again, helps but little from lack of classification of cases, methods, and mortality by each. Among the radical operators who reported death rate in complicated cases, the mortality ran from 4.5 per cent. to 30 per cent. I judge that the surgeon reporting the larger percentage understood complications to mean only general peritonitis. The same class reported the death rate of early cases from 0.6 per cent. to 1.5 per cent. One said that he never operated in early, only in abscess cases.

A distinguished surgeon of our State said that he had used the Ochsner method in three cases and all died, but he thought they would have been fatal under any treatment. He also said that he believed all cases of genuine general peritonitis died. John B. Murphy expressed the same sentiment here, I think in 1901, at the A. M. A. meeting. Three years later he retracted, saying, that he had meanwhile operated in six such cases with four recoveries.

Most of the radical operators who replied to my questions agreed that immediate operation at any stage, where diagnosis was clear, removal of appendix if possible (and it almost always is), and irrigation with normal salt solution combined with Fowler's position were the essentials—the worse the case the more rapid must be the work. Opinions differed as to the extent of peritoneal toilet advisable—also as to drainage. Several urged opium in conjunction with the above to quiet peristalsis,

and I suspect this question has more merit than most of us allow.

Many of the radicals were in line with all the essentials of the Ochsner method except the dictum of waiting for the interval. Personally I have no doubt that eventually mouth starvation, rectal feeding, gastric lavage, if indicated, and small saline enemata will be accepted as essential even in cases where the surgeon believes it either unwise or unsafe to attempt to wait for the interval.

From the foregoing I am forced to the conclusion that this very important question, which will probably outlast all others of differential treatment, viz., immediate *versus* late operation in complicated cases, will never be fairly settled, until some competent surgeon with the opportunity to treat in some one up-to-date hospital a large number of appendicitis cases, shall, on at least 500 (or better 1,000) patients, practise only the conservative or waiting policy in complicated cases and then on a like number the radical plan. The alternative would be for two competent men to make the same comparison on the same number of cases under as nearly as possible the same circumstances and surroundings.

A few words remain to be said about some of the technical details of the operation. Undoubtedly most surgeons now believe that invagination of the stump is the ideal method. To Seelig of St. Louis belongs the credit of reviving interest in the old method of ligation, amputation, and cautery of the stump. He shows that it is equally safe, as free from subsequent adhesions, fistulæ, infection, etc., as is inversion, and also avoids certain accidents, such as imbedding of the stump, where inversion was intended, with the possibility of intramural abscess of the cecum—also an occasional secondary hemorrhage from a small artery in the end of the stump not controlled by the purse string of invagination—besides being a distinct time saver.

My first five hundred appendectomies (approximately) were done by the ligation, amputation, and carbolic acid cautery method; my next two hundred (approximately) by invagination—while for several months past I have reverted to the old method with equally good results.

In all circumscribed abscess cases it is of the greatest importance to safeguard the general peritoneum by introducing beneath the edge of the incision strips of iodoform gauze before spilling a drop of pus.

If any rule can be formulated as to irrigation it would be: Do a dry operation in all circumscribed abscess and localized peritonitis cases, relying only on sponging; in diffuse peritonitis flush thoroughly with salt solution, and my experience would say search for pockets and break up adhesions as well.

In regard to the problem of drainage: beyond doubt, the peritoneum, after the bulk of infectious matter has been removed, is vastly more tolerant of the remainder than we formerly thought, as is shown by the number of infected cases recovering without drainage; however, the old adage "in cases of doubt drain" is wise policy. The cigarette drain inserted well into the pelvis, with the patient in Fowler's position, is very effective. Multiple strips of iodoform gauze placed in various directions throughout the abdomen and pelvis produces copious drainage for forty-eight hours if the top dressings are frequently changed, and in my hands have apparently saved many desperate cases. This plan has worked too well for me to allow its abandonment in selected cases.

I desire in conclusion to thank those who have so courteously assisted me by information regarding their work.

111 Belmont Avenue.

COMPARATIVE TREATMENT OF INTESTINAL AMEBIASIS.

By WILLIAM R. MOULDEN, M.D.,

WASHINGTON, D. C.

FORMER RESIDENT PHYSICIAN OF BILIBID PRISON, MANILA, P. I.

The following conclusions were deducted from a study of five hundred and forty-two cases of amebic dysentery treated in the hospitals of Bilibid Prison from June, 1903, to October, 1905.

One is immediately impressed, upon undertaking the treatment of this disease, with the uselessness of any but a direct method of attack upon the infected areas in the lower bowel. So at the outset it may be said that no medication by way of the mouth was considered in the hunt for a line of treatment offering the greatest good together with a minimum amount of discomfort and annoyance to the patient.

Upon assuming charge of the Medical Department of Bilibid Prison, with its 4,500 inmates, the quinine treatment (irrigation of the colon with an acid solution of the sulphate, of a strength of 1-500 or 1-750) was in general use throughout the Philippine Islands. As this method was in use at the prison, it was continued for about one year, the results being good, bad, and indifferent, the patients commonly complaining of pain and discomfort during its administration and of annoying head symptoms from absorption of quinine from the bowel. Under its use, moreover, the progress of a case toward convalescence was invariably slow and tedious, most cases being under treatment six weeks and over, the amebas disappearing from the stools slowly, and showing an obstinate tendency to recur. Owing to the severity of these cases the patients were invariably treated by absolute rest in bed, under a carefully arranged diet, modified according to the progress of the case, and designed to supply a maximum amount of nutriment with a minimum residue upon reaching the large intestine.

After groping about for another six months for a more satisfactory and efficient remedy, and trying in succession a number of drugs hoped to be good for the patient and bad for the ameba, the writer was fortunate in seeing an article by Dr. Moore, of the Agricultural Department, upon the use of copper in the treatment of city water supplies contaminated with low forms of vegetable life. The truly remarkable activity of the copper, in extreme dilution, upon algæ suggested its use against a member of the animal kingdom, namely, *Amœba coli*.

Rough studies of the effect of weak solutions of copper sulphate upon active amebas in fresh stools, from typical cases of amebic dysentery, soon convinced the writer that the drug had a decidedly lethal action upon the parasite, in solutions of a strength of one to ten thousand, arresting their motility and causing a shrinkage of the cell protoplasm. This seemed conclusive enough to warrant a clinical trial; so, after testing the effect of a solution of the same strength upon a normal colon and experiencing no ill-effects, ten severe typical cases were selected from new admissions to the wards for comparative study.

A rough estimate made of the number of amebas to a microscopic field (⅛ inch) from a fresh stool obtained by the use of a saturated solution of mag-

nesium sulphate was first made. The patients were then kept under observation for a few days to allow of the collection of clinical data for purposes of comparison, *i.e.* weight, record, number, and character of stools—special note being taken in regard to the amount of blood and mucus—condition of the appetite and digestion, and state of the kidneys. They were then placed upon a like diet with ten other dysentery cases in which the quinine treatment was employed.

The copper sulphate instillations were begun as follows: After placing the patient upon a specially designed inclined plane that comfortably raised the buttocks twenty-five centimeters above the level of the shoulders, thus allowing for the complete distention of the entire colon, especially at the cecum where the amebas are usually present in large numbers, by taking advantage of the fact that, as the majority of the weight of the solution is thus kept internal to the sigmoid flexure, a maximum distention of the entire colon is produced, while a minimum amount of pressure is brought to bear upon the rectum and its sensitive nervous mechanism, the colon was thoroughly irrigated, through a double-flow colon tube, with sterile water until the return was perfectly clean. After draining off all the surplus water the bowel was slowly filled with the copper solution by starting with the reservoir on a level with the anus, and slowly elevating it as the gut accommodated itself to the pressure, thus distending it to its fullest capacity without exciting contraction of the muscular walls.

As there was never any pain complained of in the use of the copper solutions, the patients seldom experienced any great difficulty in retaining it for twenty minutes; so that the entire extent of the lower bowel was thus exposed to the action of the ameba poison for sufficient time to kill off all of the parasites in the crevices of the mucous membrane and the ulcers themselves, and to some extent, perhaps, those in the deeper layers of the membrane, although it would seem, from what we know of the action of the sulphate upon tissues, that its penetrative action would be very limited.

This procedure was repeated every twelve hours, making two instillations per day. The question of frequency of treatment is an important one, for there can be no doubt that too great a number per day do infinite harm, by weakening the patient so that his resistance to the invasion of fresh areas of the mucous membrane by the ameba is so lowered that it more than counterbalances the very object aimed at by the overzealous attendant, namely, the checking of the development of the parasites by killing them off as frequently as possible. As clinical experience, as well as laboratory research, has proven that a twice daily destruction of organisms, both animal and vegetable, will sooner or later exterminate their source, it would seem wiser to depend upon two thoroughly efficient applications of the solution than to exhaust the reserve force of the individual by a needless frequency.

At 2 o'clock in the morning each patient, of the quinine as well as of the copper series, was given 50 c.c. of a saturated solution of magnesium sulphate, with the object of washing from the membrane by exosmosis as many of the amebas as possible, and by clearing out all digestive residue, securing a clean tract for the day's work. The stool resulting from this purgation was also used in making a daily estimate of the number of amebas per microscopic field.

For the convenience of the reader the bulky tabulated reports of the microscopical and clinical findings will be dispensed with, and in their stead the writer will make general extracts, from both series, upon the basis of the progress of the cases at various times during treatment:

Third Day.

Quinine Series.	Copper Series.
Patients complain of considerable pain and discomfort during the administration of the instillations, and are generally unable to retain them longer than from five to ten minutes. Stools are frequent, accompanied by tenesmus, and contain large amount of blood and mucus. Body weight same as on first day. Microscopical reports show large number of active amebas in all specimens.	Patients bear the instillations for from fifteen to twenty minutes without pain or serious discomfort. Stools are frequent, accompanied by tenesmus, and contain large amounts of mucus and blood. Body weight remains the same. Microscopical reports show slight diminution in the number of amebas per field, and a noticeable lessening of their motility.

Seventh Day.

Quinine Series.	Copper Series.
Patients still complain of discomfort during administration of instillations; also of headache and ringing in the ears. Stools retain same character as on first day, although there is some improvement in the frequency. Body weight generally the same; some slight increase in a few of the cases. Microscopical reports show large number of actively motile amebas in all the cases.	Patients retain solutions well. No pain or discomfort. Stools show well-marked improvement in blood and mucus content. Frequency and tenesmus lessened. Body weight shows a general increase, although slight, amounting to about 500 grams in most of the cases. Microscopical reports show a well-marked decrease in the number of amebas and a slight decrease in their motility.

Tenth Day.

Quinine Series.	Copper Series.
Patients continue to complain of discomfort during administration of the solutions. Absorption symptoms still in evidence. Some nausea is also present in a few cases. Stools are slightly improved in frequency and in amount of blood and mucus present. Tenesmus still very marked. Body weight: Several of the cases show increase of about 500 grams. Majority about the same as at the start. Microscopical reports show slight decrease in the number of the amebas per field; motility uninfluenced.	Patients indifferent to the quantity of solution introduced. Stools about 50 per cent. less frequent than on first day. Slight amount of blood only present. Mucus content still large. Body weight still on the increase, amounting, in some instances to a total of 1,500 grams. (About 60 per cent. of the cases.) Microscopical reports show very few amebas to a large number of fields; motility decidedly lessened.

Fifteenth Day.

Quinine Series.	Copper Series.
No change in the attitude of the patients toward the treatments. Stools have improved somewhat as to frequency, and also as to the amount of blood; mucus still abundant; tenesmus unchanged. Body weight slowly increasing, but only totaling about 800 grams in the best of the cases. Microscopical reports still show comparatively large number of amebas present; motility not changed.	Patients do not complain of pain or discomfort during the use of the solutions. Stools rarely show any blood. Quantity of mucus markedly less. Some of the cases are having slightly formed stools and no blood or mucus. Weight records still on the increase, averaging about two and a half kilos since the first day. Microscopical findings show absence of amebas in the majority of the stools. Those that are found are few and far between and have very little motility.

Twentieth Day.

QUININE SERIES.

The solutions still continue to cause discomfort and absorption symptoms.

Stools show well marked improvement in amount of blood contained and as to the number. Mucus lessening somewhat, as is also the tenesmus.

Weights are on the increase in the majority of the cases, although the best showing is 1,500 grams from the first day.

Laboratory reports show a diminishing number of amebas in the specimens from a majority of the cases.

COPPER SERIES.

Patients continue to be indifferent to the treatment.

Stools in almost all cases are formed. No blood or mucus being present in any of the cases.

Weights still on the increase, showing a general average of about three and a half kilos since the first day.

Purgation with magnesium sulphate still brings away a few parasites in some of the cases (about 40 per cent.).

Twenty-fifth Day.

QUININE SERIES.

No change in the action of the quinine solutions both locally and generally.

Stools in about 60 per cent. of the cases are about half as numerous as on the first day. Marked improvement in the amount of blood and mucus present in the favorable cases. The others are about at a standstill.

Weights in the favorable cases are steadily increasing, amounting to an average of about two and a half kilos, since the first.

Laboratory reports continue to show amebas in every case, although they are fewer in number in almost all.

COPPER SERIES.

Stools in all but one case are formed and apparently normal in every respect, no blood or mucus present. The odd case has some mucus present, stool semi-solid.

Weight records continue to show an increase in all the cases, amounting to an average of about four kilos, total since first.

Microscopical reports show absence of amebas in all but one specimen, and in this they are very difficult to find.

Thirtieth Day.

QUININE SERIES.

Some of the cases seem to have established a partial tolerance to the action of the instillations, although this is not general.

Stools in the majority of the cases are very much less frequent, and are containing less and less blood and mucus. Some 20 per cent. of the cases seem not to be making any noticeable improvement either as to frequency or amount of blood and mucus.

Weight records show increase since the twenty-fifth, in all but the two nonprogressive cases.

Microscopical reports show continued diminution in number of amebas in all but two specimens.

COPPER SERIES.

All stools are formed and normal.

Patients have gained on an average four and a half kilos.

Microscopical reports show absence of amebas from all specimens.

Thirty-fifth Day.

QUININE SERIES.

Patients still complain of discomfort during the use of the solutions.

Stools of all but two of the cases are improving in every way.

Weight records show gradual improvement in all but two cases.

Microscopical reports show that three cases failed to have amebas. Five showed very great reduction in the number of parasites, while two failed to show any material improvement.

COPPER SERIES.

All stools normal.

Patients still gaining weight, in all since the first, an average of five and a half kilos.

Microscopical examination shows no amebas in any of the ten specimens after a prolonged search through a large amount of material.

Patients taken out of the hospital and placed in Convalescent Camp, treatment being suspended.

Fortieth Day.

QUININE SERIES.

No change in reaction to the solutions.

Three patients are beginning to have formed stools; five have very great reduction in the amount of blood and mucus present, while the remaining two are still having frequent, bloody stools with large amount of mucus, and accompanied by annoying tenesmus.

Weight records of all but two cases show steady improvement.

Microscopical reports show absence of amebas in three cases; diminishing number in five, and large numbers in two.

COPPER SERIES.

All stools normal.

Weights on the increase.

No amebas found in any of the specimens obtained after purgation.

Fiftieth Day.

QUININE SERIES.

Three patients have been transferred to the convalescent ward. Two have partially formed stools, with a small amount of blood and mucus; three others show slight improvement in character of movements combined with a lessening in the number, while the remaining two are still showing but slight gains in the character and frequency.

Weight records show marked improvement in eight of the cases, and slight increase in two.

Microscopical reports show absence of amebas in the three patients' specimens sent to the convalescent ward; very few in two more; decided lessening in the number of parasites in three others; and diminishing number in the remaining two.

COPPER SERIES.

Patients have been doing regular work for a week.

Microscope failed to show amebas in any of the ten specimens obtained after the use of magnesium sulphate.

Sixtieth Day.

QUININE SERIES.

Two of the remaining seven cases were sent to the convalescent ward after going negative for five days, their stools being formed. Patients return for treatment twice daily.

Of the remaining five patients three are now having slightly formed stools with no blood and no mucus; the remaining two are beginning to pass soft stools containing a diminishing amount of blood and mucus.

The weight reports of the worst of the cases are now showing a very marked increase over the last record. Others still continue to improve rapidly.

Amebas found inconstantly in the better of the five cases; in the two slow cases they are fewer in number, but constant.

The convalescents were kept under observation for about a month after leaving the hospital, and, as far as is known, no case of the copper series had a return of the disease. The quinine cases, however, were not so fortunate, two of the ten suffering a relapse about a month after suspension of treatment. The hospital records show a large number of instances of men being admitted for from two to four times for this affection within a space of one year.

After the second month of this treatment all cases of amebic dysentery admitted to the hospital were placed upon the copper treatment, and its extended use more than confirmed the results obtained in the trial series.

A word in regard to the temperature and strength of the copper solutions may not be amiss, as experience showed that attention to every minor detail

drew compound interest in the results of treatment. As a general thing most cases improved more rapidly under the use of very hot instillations, due, no doubt, to improved penetrative power and to the reaction brought about by the heat in the mucous membrane. Clinical experience proved that most patients could bear comfortably a temperature of from 106° to 110° F., and although profuse perspiration always occurred, no unfavorable symptoms ever resulted.

In some of the more extensively ulcerated cases, roughly determined by the amount of blood and mucus present in the stools, more rapid results were obtained by the use of a stronger solution. No case failed to react favorably to a solution of a strength of 1-6,000. A stronger fluid than this was never used.

The very rapid gain in weight in almost all the cases was due, it is thought, to the fact that, almost without exception, the dysentery cases were new arrivals from the field, and consequently were suffering from chase-fatigue as well as from the disease itself. The greater gain recorded in the copper series was no doubt due to the more rapid recovery from the disease drain; it is also thought, from general observation of the cases, that some tonic action resulted from the use of the copper solutions, possibly from some slight absorption through the mucous membrane. However this may be, the facts are that all cases so treated acted as patients under the influence of an alterative, such as arsenic, as shown by a vigorous appetite and rapid increase in weight.

In conclusion, it may be said that the copper seems to have a more or less selective action upon *Amœba coli* as well as upon the lower forms of vegetable life, such as the algæ; that copper solutions are far better borne by the patient than quinine; that patients make a more rapid recovery under its use, gaining flesh and strength at least twenty-five per cent. more rapidly than under any other method known to the writer; and, most important of all, the cases stay cured, provided, of course, that treatment is kept up a reasonable time after the disappearance of the amebas from the stools.

As the cases treated by copper number over two hundred, it seems reasonable to conclude that the method is based upon sufficient ground to warrant its thorough trial by anyone interested in this subject.

1305 Rhode Island Avenue.

A REVIEW OF THE EVOLUTION OF THE MODERN SURGICAL TREATMENT OF FIBROID TUMORS OF THE UTERUS.*

By LeROY BROUN, M.D.,

NEW YORK.

In witnessing the finished removal of a fibroid tumor of the uterus by the surgeon of the present day, and in seeing the even after-recovery of the patient, we forget for the time the difficulties of some years past and the disaster and stormy recovery which was the lot of the patient who had the Spartan courage to undergo such an ordeal. It cannot but be of interest to glance briefly at some of the former difficulties and dangers necessarily encountered during the earlier surgery upon fibroids, and to review for a few moments the steps through which the present operations have been evolved.

As soon as it was demonstrated that the peritoneal cavity could be invaded with safety to the patient, surgeons turned their skill to the removal of ovarian tumors. These were the easier since their contents could be emptied, leaving a pedicle comparatively small and the more rapidly secured. It is to Ephraim McDowell, of Danville, Kentucky, that the honor is due of performing the first ovariotomy. He removed the tumor in his office in December, 1809, ligating the pedicle, dropping it back, and drawing the long end of the silk ligature through the lower angle of the abdominal wound. His individuality and personal courage were of the highest order. None were bold enough to attempt the removal of the solid tumors of the uterus until Kimball, an American surgeon of Lowell, Mass., in 1853 removed successfully such a tumor by ligating the thick stump, dropping the pedicle and drawing the end of the ligature through the abdominal wound. Operations of like character by Kimball and others who emulated his bold effort resulted so disastrously to the patients as to prevent for the time further efforts in this line. It was not until 1873, twenty years after Kimball's first operation, that surgeons began again to direct their attention to the removal of these tumors. During this interval efforts to benefit the sufferers from such neoplasms were confined to bringing about a premature menopause through removing the tubes and ovaries, it being found that in some instances such a removal caused a cessation of the hemorrhages and prevented a further growth of the mass. Unfortunately, however, that was not always true, and Tait himself, who appears to be the originator of this procedure, admitted that frequently the results were not attainable under a year and a half or two years. He further admitted that such a removal did not affect pedunculated fibroids or those of fibrocystic character. It was further recognized that it was impossible to remove the appendages in many instances, they being out of reach by being imbedded in adhesions or situated behind the solid mass and difficult to get at except through what was then regarded as an extensive procedure. Failure to accomplish the desired results of putting a stop to the bleeding, or effecting a cessation of the growth of these tumors by removal of the ovaries, and the inability to remove both in some instances caused surgeons to undertake again the removal of these masses. The method adopted was to deliver the tumor through a large abdominal opening and encircle the base with a clamp which was afterwards tightly screwed up. The tumor was then cut away, the clamp holding the stump outside of the abdominal opening until adhesions had formed and the stump enclosed between the jaws of the clamp had sloughed away. Spencer Wells and Keith are both prominently associated with this character of operation, Spencer Wells reporting, in 1878, twenty-four operations with a mortality of 62.5 per cent., while Keith, about ten years later, stated the death rate was 25 per cent. or higher, and says that the operation had done more harm than good.

This extraperitoneal treatment of the stump following hysterectomy was developed to the full extent by Pean, Hegar, Spencer Wells, Keith, Koeberle, and Bantock. The clamp was discarded, and in its place were substituted the pins and *serre-nœud* of Koeberle. Here the operation was practically the same as by the clamp. The tumor was delivered through the abdomen.

*Read before the West End Medical Society of New York City.

The wire loop was made to encircle it as far down as possible to avoid including the top of the bladder. The loop was then tightened as much as possible. Two pins were passed through the stump above the loop, the free ends of the pins resting on the abdominal wall and holding the stump in this position until all sloughing had ceased. By this method the lowest mortality was about one patient in every four operated on, varying from this to one in two or three dying. It continued to be the operation of election up to about 1890. The high mortality of from 25 to 50 per cent. resulting from the extraperitoneal fixation of the stump caused some operators to seek other means of avoiding these dangers, and while the majority of operators were still using the wire loop of Koeberle, Schroeder ligated the broad ligaments down to the cervix, removing the tumor by a wedge-shaped incision and sewing up the cervix. His death rate was high, one in three, chiefly from secondary hemorrhage. Zweifel followed shortly after by a modification of Schroeder's method, in stitching over the entire broad ligaments including the cervix. His results were excellent, and in 1889 he reported twenty-two successful cases.

The stump of the cervix left after removing the tumor was the focus around which all dangers centered. If ligated its circulation was cut off and sloughing resulted, or the ligation was not sufficient to control the bleeding from the cut ends of the uterine artery and subsequent hemorrhage resulted. At this juncture Goffe, in 1888, devised and carried out a method of making two distinct peritoneal flaps, anteriorly and posteriorly, ligating the broad ligaments, together with the stump of the cervix, uniting the peritoneal flaps and using the reamed-out cervix as a drainage canal for suppuration under the flaps. He reported three successful cases in 1890. About the same time, in 1888, Dr. Mary Dixon Jones, of Brooklyn, suggested the removal of the cervix as a logical way of avoiding the dangers of its retention. It is strange that this was not suggested earlier. Dr. Lewis A. Stimson also, in 1889, pointed out the importance of tying the ovarian and uterine arteries individually as a preliminary step to removing the uterus and its fibroids. By the suggestion of Dr. Stimson the tying of large masses in a single ligature, the former custom, was avoided, as was also the frequently resulting secondary hemorrhage. The transition period of the surgical treatment of fibroids may then be said to be from 1890 to 1896. During this time the *serre-nœud* of Koeberle ceased to have a general use, though Bantock advocated it as late as 1894, and Knowsley Thornton, and Malcolm as late as 1896 and 1897. The operations suggested by Zweifel and Goffe, though practised by some operators, were not the ones most generally adopted.

The removal of the entire tumor with the cervix was the method most generally chosen, and became widely accepted after the appearance of the detailed technique published by Christopher Martin in 1896. At the same time the important modification of the Zweifel operation was made in tying the uterine arteries, thus avoiding subsequent hemorrhage. While the development of these two methods, the one of leaving the cervix after the removal of the tumor, and the other of removing the cervix with the tumor, was being improved, another method of removing the small fibroid tumors through the vagina was being ably advocated and pushed to surgical excellence by Landau, Pean, Jacobs, and Segond abroad, and by Pryor and Polk of America. At the same time the suggestion of Goulet and Martin of tying the uterine artery was practised to some extent. The methods now in vogue are: Vaginal hysterectomy by Morcellation; total abdominal hysterectomy; supravaginal hysterectomy.

The removal of the fibroid diseased uterus through the vagina is restricted to tumors which have reached only such size as still to exist in the pelvis. Those that are larger and exist as abdominal tumors cannot with ease be attacked by this method. The vaginal operation is essentially foreign, being carried to great perfection by Landau, Pean, Segond, and Jacobs, and in America by the late Dr. Pryor, and at present it is ably upheld by Dr. Goffe.

A recent examination of the records of the Woman's Hospital shows that within the seven years ending in 1902, there were done one thousand seven hundred and eighty-three laparotomies and vaginal sections. It is interesting to note in these records the unconscious trend of opinion among those connected with this hospital during the time mentioned. In 1897, one hundred and sixty-nine operations were done through the abdomen and seventy-one were done through the vagina. In 1899, one hundred and ninety-nine operations were through the abdomen and fifty-six through the vagina. In 1900, two hundred and eighty-two operations were through the abdomen and twenty-six through the vagina. This gradual abandoning of the vaginal route in favor of that by the abdomen was an unconscious step on the part of all of us, and was the result of an effort to do more conservative work and to save all parts that could be of any possible service to the patient. The importance of saving parts of ovaries and parts of the tubes began to be appreciated to a greater extent. The ability to separate intelligently under the eye adhesions of the intestines was self-evident. The frequency of a complicating disease of the appendix and the inability to treat such conditions through the vaginal incision was recognized. The possibility and actual occurrence of adhesions of knuckles of intestines to the vaginal scars began to come home to us. Coe reported two such cases and collected eight others. Two occurred in the writer's practice; all were fatal. These are the reasons why the vaginal hysterectomy was abandoned except in special instances of the methods by the abdomen. I regard the supravaginal method as being much the more surgical.

In a series of three hundred and forty-five cases of supravaginal hysterectomy collected by Noble, representing the work of five American surgeons, the death rate was 4.9 per cent. as against 10 per cent. in one hundred cases of total hysterectomies. In a collection by Olshausen of eight hundred and six cases of supravaginal hysterectomy the mortality was 5.6 per cent. as against a mortality of 9.6 per cent. in a collection of five hundred and twenty cases of total extirpation. In the supravaginal operation there are no sloughing areas to keep clean and to heal by granulation. The vault of the vagina is left intact and its resiliency is maintained. The recovery of the patient is less painful, for the removal of drainage gauze is always attended with pain. The surgical care of the patient is also shorter than that following a total hysterectomy. Aside from the above reasons in favor of leaving the cervix when possible, another and very important element is that of

time saved. The removal of the cervix alone does not involve many additional minutes. There are, however, some descending branches of the uterine artery which supply the cervix and vagina; often they are poorly developed, and do not give any trouble when cut. They are, however, at times the source of much annoyance, and the time consumed in arresting all bleeding can add much to the gravity of the operation.

Under certain conditions the interest of the patient is conserved by doing a total hysterectomy and employing drainage. As such can be cited cases with adhesions and much raw oozing surface exposed, or of suppurating affections of the appendages, complicating the fibroid tumor in which some necrotic areas must be left, or, as stated, when the fibroid tumor has developed between the folds of the broad ligament, leaving a large oozing surface after removal. In all such cases it is necessary that the oozing be stopped; that the raw surfaces be kept from coming in contact with coils of intestine, and that necrotic areas be cut off from the general peritoneal cavity. This can be done by removing the cervix, introducing the free ends of gauze drainage strips through the opening into the vagina, and covering the areas in question with a light packing of the remainder of the gauze. After the edges of the broad ligament are united and closed over the stump of the cervix in a supravaginal hysterectomy, I think it unwise to drain the space between the peritoneal flaps and the cervical stump. Experience has shown that better results are obtained by closing the cut edges of the cervix. The method of draining is by divulsing the canal of the stump and passing through it into the vagina a small wick of gauze. As a result of this practice the intervening space occasionally becomes septic from an extension of an infection from below. With a rigid aseptic technique the infection of this space should never occur when drainage is omitted and the stump closed.

Concerning myomectomy, while the removal of these pathological growths from the uterus and leaving that organ intact is the acme of surgery and a result always to be sought, there is, however, a limit to such efforts, and an operation which ordinarily would be regarded as an exponent of conservatism can become most radical by endangering the patient's chances of recovery, or by leaving a uterus whose tissue is so degenerated in fibroid bearing as to subject the patient to a subsequent operation at a later time for the removal of new fibroids given birth by the diseased structure of the uterus. If there are only a few fibroids in the uterus, and if they can be removed without leaving a macerated uterine body in which, through the numerous sutures introduced, it is probable that the circulation will be interfered with, myomectomy is the operation of election. If, however, there is a possibility of such a circulatory interference and death of some portions of the uterine tissue it would be eminently hazardous to jeopardize the patient's recovery by such a procedure. In such cases the uterus should be removed with the fibroids.

At the time when the mortality attending the removal of fibroid tumors was high the benign character of these growths was made prominent in our minds, and the fact that the patient could live in passable comfort outweighed the dangers attendant upon efforts at their removal. Coincident with the decrease of the removal death rate a more complete knowledge of the character of these tumors was being obtained, also of their indirect effect upon other organs of the body and upon the general health of the patient.

We know that the menopause is not always the haven we had been taught to expect. In tumors in which the fibrous tissue predominates, making the hard variety, a contraction and shrinking in size is at times noticed after the cessation of the menstruation; but in those having the muscular elements predominating constituting the myomatous type, as also in the fibrocystis tumors and edematous tumors, the cessation of the growth does not take place at the menopause. We know also that the menopause does not come on in the presence of these growths as early as normally, in fact the cessation of menstruation is ordinarily delayed from five to ten years. Bishop mentions an instance in his own practice of a patient who, though sixty, still menstruated regularly.

In the progress of the growth of the tumor, disturbances in its circulation frequently result, causing adhesions to the organs adjacent to it, rendering its removal, when necessary from urgent causes, more dangerous to the patient. During the course of its development, not infrequently it extends between the folds of the broad ligament, dissecting up the pelvic peritoneum. The tumor, being solid, does not give as an ovarian cyst would do, and whether the development is under the peritoneum or intrapelvic it at times becomes wedged between the bony boundaries, and, pressing on the ureters, causes a pyonephrosis—a degeneration of the kidneys and ultimate death.

Fibroid tumors of the uterus do not exist alone as the only diseased condition present in the individual. There are commonly associated with them inflammatory states of the tuboovarian adnexa, of one or both sides. Such complications when going on to a purulent condition endanger within themselves the life of the patient. The long-continued drain through the profuse hemorrhages attendant upon a majority of fibroid tumors so deplete and weaken the physical state of the patient as frequently to be the indirect cause of her death through some intercurrent disease at some period of their existence. Fibroid tumors may undergo a necrotic change. Especially is this true of the submucous variety, and it was also not an uncommon sequel of the electrical treatment by puncture of some years past. The sloughing of these tumors caused by an interference in their circulation is one of the gravest complications that can arise in connection with their presence, rendering a fatal termination positive unless relief is obtained, and magnifying at the time of the operation the danger of their removal. Another form of degeneration of these tumors is the sarcomatous change known to take place among them.

Fibroid tumors may remain quiescent for a time and afterwards begin to rapidly increase in size, becoming fibrocystic or edematous. These changes in the light of modern pathology do not bode good to the patient. Graves, of the Free Hospital for Women in Boston, has devoted considerable time to the study of microscopic sections of these tumors. At a meeting of the Woman's Hospital Society of the past year, he stated that he had then examined thirty-three uterine myomata, of which three showed sarcomatous change. Of the entire number examined four were cystic or edematous. Those found to have been sarcomatous were from these four. He calls attention to the report of Menge, in which two sarcomata existed in sixty-three tumors examined. There were two fibrocystic tumors among

all examined; both of these showed the sarcomatous changes. There is, therefore, as he states, unquestionably a close relation existing between the various forms of degenerative changes taking place in fibroid tumors, whether fibrocystic, edematous, or sarcomatous, and a lighting up of an active growth in a tumor formerly quiescent should be regarded with grave concern. The inference that sarcomatous changes in fibroid tumors are as frequent as would appear from the reference to the examinations of Graves and Menge would, however, hardly be correct. Our present knowledge would indicate that such changes do not occur in over 1 per cent. or less of tumors removed.

The time is not so far behind us that the majority of those present cannot recall the size to which ovarian tumors were formerly allowed to grow before their removal was undertaken. One of the points then impressed upon students in the differential diagnosis of these conditions was the drawn cachectic countenance known as the "ovarian facies" of the patient having such a large tumor. We know now that this expression was due to a physical exhaustion largely as a result of a malignant change taking place within the tumor itself. The profession is now of one mind that all ovarian tumors should be regarded as malignant unless proved not to be so by removal and examination. As a result patients with ovarian cysts are counseled to submit to an early removal, and it is now rare that we come in contact with those of large size. In view of this well-established opinion among all physicians concerning the early removal of ovarian cysts, it is anomalous that there should be in so many of us the habit of procrastinating and temporizing when it concerns fibroid tumors of the uterus. They are as much a menace to the life and health of the patient. They are known to undergo malignant change, and on account of being solid and not adapting themselves to the adjacent structures as in ovarian cysts disease of the kidneys may result from ureteral pressure. Profound invalidism is a result of the profuse hemorrhages in tumors of a submucous and intramural type, giving rise to anemia and cardiac disease, and they are the cause of sudden deaths, as also of emboli and of pulmonary edema. Webster in a recent discussion of this subject before the Philadelphia Obstetrical Society, states that in 210 patients from whom he had removed fibroid tumors twenty-five had cardiovascular symptoms.

Bishop in his treatise on uterine fibroma gives a large collection of authenticated reports of deaths resulting from unoperated fibroid tumors of the uterus. He cites Winkel's statistics giving 10 per cent. of patients with such tumors, and who were not operated on, as dying either sooner or later as a result of the neoplasms. Noble, in a recent paper on the complications of fibroids, gives as a result of a study of a large collection of cases that had been operated on, that almost 15 per cent. of the patients would have died from changes in the tumor itself if operations had not been done, and that an equal percentage would have died from complications attending the tumor.

From such an array of facts it is hard to conceive how we can in conserving the interests of the patient, do otherwise than advise an early removal of such fibroid tumors as may exist, knowing that the sooner such a course is adopted the safer will be the operation and the greater will be the likelihood of saving the uterus and removing the tumors alone.

In closing I wish to accentuate my conviction that we conserve the interest of our patients when we advise the discarding of palliative measures and counsel the removal of fibroid tumors, whether they are giving rise to distressing symptoms or not. This belief is based on the knowledge that the death rate from the removal is now less than 1 per cent. in individual statistics, to 4 per cent. in combined statistics, while with patients who have fibroid tumors and are not given operation the mortality directly and indirectly the result of these tumors is at least 10 per cent. Further, in removing the intrapelvic smaller tumors there is less risk to the patient and a greater possibility of saving the uterus.

This is not, however, intended to include the small fibrous nodules recognized only by one with trained touch and occurring in women near the menopause. Such conditions need no interference unless they show a tendency to increase in size.

THE ADMINISTRATION OF DRUGS TO CONCURRENTLY RETARD AND STIMULATE SYSTEMIC OXIDATION.

By BERNARD OETTINGER, M.D.,

DENVER, COLO.

In a previous communication[1] I took the position that although the presence of methemoglobin in the blood in sufficient amount (according to Ad. Dennig, 66 2-3 per cent.) results in death, nevertheless a methemoglobinemia of nontoxic proportions may exist, and hence that this blood condition must not invariably be regarded as deleterious to conservative metabolism. More than this, that I believed therapy empirically makes use of this blood change to aid in conservation of nutrition. Cited as examples were the use of amyl nitrite for angina pectoris, pyridin inhalations in asthmatic attacks, potassium chlorate administered for a limited period in acute infections, and its occasional use long continued and with success to prevent recurrent abortions, the bromine salts in epilepsy, the employment of iron as the perchloride in chorea minor and as used by the older practitioners in sepsis, Lugol's solution and iron iodide in scrofulous and cachectic conditions, potassium permanganate in anemia, quinic acid (yielding on decomposition pyrocatechin and hydrochinon) in gout, etc. It was pointed out that good accrued to the patient from slight methemoglobinemia effecting an increased oxidation of a selective character, viz., an oxidation through methemoglobin of intermediate products of metabolism which in diseased conditions accumulate in abnormal amounts in the blood, and at the same time an oxidation without effect upon the normal tissues. Such selective action occurs because the products of tissue catabolism being more powerful reducing agents than the tissues themselves are able to take oxygen from methemoglobin—a more stable oxygen compound than oxyhemoglobin—although the tissues cannot. Thus in face of the profession's belief that a methemoglobinemia in any degree is a toxemia, a serviceable empiricism yet enables us to utilize methemoglobin oxidation to effect elimination of toxic and inert elements of regressive metabolism as end-products. In connection with the foregoing hypothesis, I now advance a second to explain rationally the concomitant use of another class of drugs whose position as regards systemic oxidation is diametrically opposed to those previously considered.

Constitutional treatment of disease, both acute and chronic, finds continued reiteration in the use of iron, strychnine, quinine, and arsenic, to which, if chronic dyscrasias be alone considered, we may add phosphorus. Of these the specifically tonic effect of iron upon the blood and of strychnine upon the nervous system fully explains their employment, at least from the viewpoint of tried empiricism. But what of the remaining three? Quinine, arsenic, and phosphorus, possessing in common good repute as systemic alteratives, are nevertheless given individually under widely different indications. We give quinine for specific effect in acute malaria to kill the plasmodia, also for immediate effect in other acute diseases with fever, but here as an antipyretic; again in smaller dose in chronic dyscrasias (including malaria) with or without fever. We use arsenic in acute toxemias such as chorea minor and Graves' disease, also in chronic states of malnutrition (including malaria) where, as a rule, but not invariably, fever is absent. Further, we select arsenic for its stimulating effect upon the organs which produce corpuscular elements of the blood. We consider phosphorus if intent upon some specific effect upon bone tissue, otherwise as an alterative in chronic neural affections. Such indications (barring quinine in malaria) are, as regards each of these drugs, too generalized to give an impression of exactness. Some connection between them is established by the manner in which their several indications touch each other as it were, at tangential points. Yet without a relationship more clearly fixed the frequent concomitant use of these drugs for general tonic effect remains obscure. The explanation to my mind lies here—they possess in common the property of retarding tissue oxidation. As to quinine, Cushny,[2] referring to Binz's experiments, says: "The oxidizing action of drawn blood was shown to be diminished (by quinine). Immediately after its issue from the vessels, the unpoisoned blood undergoes a diminution of its alkalinity from the oxidation of some unknown substances at the expense of the hemoglobin, which is partially reduced. This acid fermentation is prevented by the addition of quinine to the blood. Even when pieces of tissue are added and the reduction of the arterial blood would ordinarily be much accelerated, quinine prevents or retards the change. A similar inhibition of the oxidizing action of the blood is shown by its failure to form the blue oxidation product of guaiac or to decolorize indigo when it is applied to blood along with quinine. From these experiments (and others) the inference is drawn that quinine hinders the action of the oxidizing ferment of the blood and tissues." That phosphorus and arsenic also retard tissue oxidation is an accepted fact. Orfila and Rigaut[3] showed that in dogs poisoned by phosphorus, putrefaction was remarkably retarded. The use of arsenic to retard tissue decomposition is common. The appearance of lactic acid, sugar, and albumin in the urine in phosphorus poisoning is attributed by Araki to insufficient oxidation, and Cushny says that this statement which makes lack of oxidation an essential part in phosphorus poisoning merely confirms the impressions of many earlier writers. The presence of the same products in the urine in arsenical intoxication, together with generalized fatty degeneration common to poisoning by phosphorus and arsenic, admits of the same explanation, viz., inhibited systemic oxidation. Now we know that in disease regressive metabolism is always increased, a condition not less true of chronic morbid states (considered relatively to assimilation) than of acute diseases with fever, although the fact may be more palpable in the latter. Against such increased catabolic tissue oxidation, the use of a substance (selected also in accordance with other systemic affinities since the action of drugs is not single) which would retard oxidation must be valuable because of its conserving effect. Yet in therapeutic dose such a drug, although effective, could not entirely inhibit an increased metabolism, which, therefore, would still produce an abnormally great amount of tissue products to be eliminated. That complete oxidation of these augmented intermediate compounds by oxygen furnished through the lungs is difficult, is shown by the dyspnea noted not only in fever conditions but also in chronic states of air hunger without fever, such as simple anemia, asthma, etc. Here the selective oxidation through methemoglobin comes in good stead in that only regressive tissue products are oxidized, the tissues themselves remaining unaffected. These hypotheses therefore serve to explain what at first glance may appear paradoxical, viz., the simultaneous administration of drugs to effect concurrent retardation and stimulation of systemic oxidation.

The theory advanced as to the rôle of certain oxidation-retarding drugs falls in with accepted medical practice, that relating to the manner in which methemoglobin producers are believed to act beneficently is entirely heterodox. Perhaps the consideration of both in relation to one another may help to gain for therapeutic methemoglobinemia some recog nition of its utility, and thus recall the same from its place of undeserved disrepute.

Clinical and Experimental Study of the Action of Mercuric Cataphoresis in the Treatment of Cancer.—Amédée Granger declares that in mercuric cataphoresis we have a means of destroying not only the malignant growth, but the proliferations into the apparently healthy tissue, rendering the latter sterile and stimulating its cells to greater physiological activity. This last effect is due to the selective action of the current which forces the diffused chemicals along the paths of cancer proliferations. Cancer cells succumb more quickly to the diffused chemicals than do normal cells. It is capable of producing an autoinfection of the edges of the destroyed area, because no infected cells of germs can exist within the affected radius of its energy. After the application, the patients make rapid recoveries because they have not been weakened by the loss of blood attending the use of the knife or curette. Although using this method on most unfavorable cases, the writer has had only one death during an application and he is convinced that the method was not responsible for this fatal result. This method has been found of inestimable value as a cure or palliative for growths in the mouth. The cosmetic results have been excellent in the cured cases. Although the writer believes that some improvement and occasional cures may be expected from this method in inoperable cases, he is convinced that it should not be reserved for such cases, but should be used in operable ones as early as possible and before the local disease becomes general.—*Journal of Advanced Therapeutics.*

TUBERCULOSIS AND PREGNANCY.

IT is not always an easy matter to decide what shall be done in any given case in which the two conditions mentioned above are associated, for although the question has been much discussed no definite conclusions of any consequence have been formulated. The principal reason for this uncertainty may be traced to the fact that it is a difficult matter to formulate a rule of action which shall have a general application, and it has been found that better success will attend a procedure which is based upon the indications present in each individual case. Tuberculosis is a serious complication of pregnancy, and as such it has been made the subject of careful study by numerous observers. These studies have supplied us with many valuable data from which certain helpful conclusions may be drawn. In order to make use of these in formulating a prognosis, a grouping of the cases already studied is necessary. This has been undertaken by Rosthorn of Berlin, who was assisted in the work by A. Fraenkel (*Monatsschrift für Geburtshilfe und Gynäkologie,* June, 1906). In a clinical material including 1,500 cases of pregnancy, a definite pulmonary tuberculosis was present in 25 (1.6 per cent.). The comparative frequency of tuberculosis in the general community would seem to imply that there must, in addition, have been many latent or circumscribed processes which escaped observation. In sixteen of the cases noted (64 per cent.) the general condition became worse, and in nine this took place very rapidly. The number of deaths was tion. In sixteen of the cases noted (64 per cent.) were particularly unfavorable in which the tuberculous process first appeared during pregnancy. In contrast to this it appears that in other instances in which a tuberculosis is already present one or even more pregnancies may occur without the pulmonary process being in any way unfavorably affected.

From our present knowledge of the subject it seems, therefore, reasonable to infer that pregnancy is relatively without influence in tuberculous women who have for several years experienced no advance of the disease and are considered practically cured, in whom the pulmonary signs are favorable, in whom the general nutrition is good, and when there has been no fever for over a year and no hemoptysis has occurred. Similarly, pregnancy may continue without danger in those cases in which there are evidences of a more recent but well localized apical process, without much elevation of temperature, which does not advance during this time. In certain instances, however, the prognosis is less favorable. That is to say, when we are dealing with an active florid process, accompanied by continued high fever, or when the fever, although not high, is continuous, even while the objective findings are not marked, and fails to decline under proper treatment. The prognosis also seems to be unfavorable when the disease is not restricted to the apices, but involves the middle and lower lobes of the lung or when the pulmonary lesion is complicated by disease of the heart, the urogenital system, the gastrointestinal tract, or other organs. Laryngeal tuberculosis also constitutes a very unfavorable complication.

It will be seen, however, that in all this we have nothing absolutely definite to guide us in any given case, and the individual factors must always remain the deciding features. Rosthorn's conclusions are formulated in the following general statements: In mild, as well as in moderate and severe cases, whether febrile or nonfebrile, it is advisable to observe an expectant attitude. The hygiene of pregnancy should receive particular attention, and the tuberculous lesion itself must be most carefully watched. Rest and climatic treatment are indicated, for the tuberculous process may be halted, or even relatively cured, during any period of pregnancy. As regards the interruption of the pregnancy, it has been found that abortion is much safer than the induction of premature labor, for a woman who survives the latter would, in most instances, have made even a better recovery if her pregnancy had been allowed to go to term. It is rarely possible to save either mother or child by this means, who would have succumbed without it. Abortion, however, must always be considered, according to Rosthorn, when there is present a destructive febrile process, whether old or recent, or even a process which is less severe, but is accompanied by certain complications, chief among them being laryngeal tuberculosis. In addition to these, relatively cured patients who, despite appropriate treatment, rapidly lose flesh, should also be looked upon as subjects for this operation. The child does not enter as a factor in these cases, because healthy children may be born even when the mother is markedly tuberculous, and the intrauterine transmission of the disease, if it ever occurs, is a rarity.

THE EDUCATION OF THE DULLARD IN THE PUBLIC SCHOOL.

INSTRUCTION of the individual, rather than of the class, should be the rule in the education of the young, but unfortunately there are many factors which interfere with this ideal, and they are of such a character that an effective remedy can hardly be hoped for. In one respect, however, it is essential that some distinction be recognized, and that is in regard to the mental equipment of children. Although generally assumed to be so in our public school system, this is by no means uniform, and the failure to note this fact is productive of both harm and distress. It is, of course, a difficult matter to draw an exact line between the children who are normally bright and those who exhibit some slight recession from this

standard, which is termed either stupidity or laziness, and which would force them into a class by themselves. Our classes, particularly in the public schools, are ordinarily too large to permit of any individual attention by the teacher to children who may be only slightly backward in their mental equipment, and yet this omission may be the means of starting the unfortunate little victims on a downward career. For the inability to keep up with their class excites their shame, and truancy, with its attendant evils, is the result. In addition to these mildly defective children, there are some of a more advanced type in whom other deficiencies are also present, which render them unfit to associate with normal school children, and to whom they often constitute a real menace.

It has become a common form of condemnation to say that such defective children should never be allowed in school, but, as pointed out by J. P. Haney in an article in the *Annals of Gynecology and Pediatry* for June, 1906, it would be far more proper to say that they should never be allowed out of school, or at least not until they have been taught some measure of self-control. As the author truly states, the education of these defective children cannot be undertaken in the ordinary class room. The training must be mental, physical, and moral, and must include hygienic treatment. It must be elemental in character and sympathetic in administration. Dr. Haney points to the necessity of securing special teachers for such work, and says that they should be paid equally with the best paid of the system. Women of a sanguine temperament, cheerful, optimistic, and quiet in manner, are to be preferred. The teaching must be individual, and therefore a class should be limited to fifteen members. Objective rather than didactic teaching should be followed, so that the pupils learn by handling things, and not by the hearsay of teacher or textbook. Mental operations should always be made subsidiary to manual operations, for the "joy of successful constructive achievement and power acts as a keen spur to interest and to mental development." Proper medical supervision and physical exercise are also two important factors in the successful education of these defective children, and in addition to this their morals and manners must also be cultivated.

It would seem that money spent in this way would be well spent, yet we find that very few of our large cities have made any provisions in their public school system for education of this kind. New York has successfully conducted a number of these classes during the past five years, but in only five or six others has a similar attempt been made to provide for defective children. The State, using the term in its sociological aspect, has been taught to be more solicitous than formerly in regard to infectious diseases and their power of physical contamination. It should display an equal solicitude towards its mental weaklings, conscious of their power of moral contamination. Dr. Haney's communication is of extreme interest and deserves a wide reading by all who are interested—and who is not—in the mental and moral training of our embryo citizens.

RECIPROCITY IN MEDICAL LICENSURE.

In his presidential address before the American Medical Association in Boston, Dr. William J. Mayo brought up the subject of reciprocity in medical licensure between the various States of the Union and urged that an agreement be reached between the State examining boards whereby a legal practitioner in one State might be recognized as such in every other State. Theoretically, this would be a very desirable state of affairs, but practically, at least until the older generation of physicians has passed away, it is impossible. It seems at first sight unjust that a practising physician or surgeon, in New York let us say, who has been twenty or thirty or forty years in the active exercise of his profession, and is a thoroughly competent man, perhaps with a national or an international reputation, is legally only a layman in New Jersey or Connecticut, and if he attempts to practise medicine in either of the adjacent States, or any other but his own, exposes himself to arrest and punishment as a lawbreaker. Many who had not given thought to the matter would be inclined to agree with Dr. Mayo that such conditions are "well-nigh intolerable and restrain the individual freedom guaranteed by the Constitution," though few, we think, are so ignorant of the history of their country as to follow him in the assertion that "the boundaries between the States are imaginary lines." If the State boundaries are imaginary lines so far as medical laws go, then they are equally intangible as regards other laws, and State legislatures and State courts become at once needless and expensive luxuries, and the sooner they are done away with the better for the taxpayers and the lawbreakers. The doctrine of States' Rights was shorn of some of its exaggeration in the '60s, but it exists just as firmly established now as then, and it will and must exist so long as the present Constitution of the United States is in force. The State boundaries are very real lines, delimiting sovereign States and opposing impassable barriers to the validity of many laws, among which are the laws regulating the practice of medicine. The president of the American Medical Association, or any individual member thereof, cannot pass this "imaginary line" in the practice of his profession without transgressing the law. And it is well that it is so.

We do not mean that we are opposed to reciprocity in medical licensure. On the contrary, we are in favor of the fullest reciprocity compatible with the laws of the individual States. But the laws of the States must be respected, and, as Dr. James A. Egan, Secretary of the Illinois State Board of Health, has well shown, in a paper read before the Illinois State Medical Society at its meeting in Springfield in May, 1906, these laws, in many if not all of the States, make unrestricted reciprocity impossible. In the case of Illinois, for example, the law distinctly states that a license to practise medicine shall be given only after satisfactory examination; and in making provision for reciprocity it further states that this shall be allowed only in case of certificates issued by other boards after examination. The old practitioner, that is, the one who was in practice before any medical law was passed in his State, and who was consequently licensed without examination, is therefore barred from practice in Illinois without an examina-

tion either in his own State, if that has a reciprocity agreement with Illinois, or in Illinois. This may work a hardship in individual cases, but so do many laws which are enacted for the good of the community and not for the benefit of the individual.

Illinois has, however, gone farther than any other State, so far as we know, to mitigate the possible hardships of the law in this respect. The State Board of Health, which is the examining board in Illinois, has adopted a resolution allowing a credit of 5 per cent. on the required 75 per cent. of successful answers, in its examination, for each five years the candidate has been in active practice. The reason for this rebate in the requirements is evident. A man who has been in practice for twenty or thirty years has naturally forgotten much in the elementary branches—useful and necessary as preliminary to a comprehension of his science, but not essential to the successful practice of his art. The Illinois State Board, therefore, makes provision for this lapsus by requiring less of the old practitioner, reducing his minimum by 30 per cent. if he has been in practice thirty years. We cannot imagine anything more fair or more considerate of the "old man" whose *wanderlust* impels him to change the scene of his professional ability. The State law insists, and we think wisely, upon an examination as a preliminary to practice, but Illinois has gone to the limit in reducing the hardships of this law to a minimum. If all the other States would follow the example set by Illinois, universal reciprocity would be as near to a realization as it ever can be, and the chimerical dream of federal licensure would be set at rest. The practice of medicine is not, and never can be, within the provision of our interstate laws; it is a matter to be regulated by the laws of each individual State; but the hardships resulting in individual cases from the enforcement of these salutary laws could be very materially mitigated by the universal adoption of some such regulation as that which Dr. Egan says has been adopted by the Illinois State Board of Health.

The Spontaneous Cure of Cancer.

Experimental research has apparently shown that there are certain immune forces existing in the body which are antagonistic to the growth of cancer. Mice affected with carcinoma have been reported as spontaneously cured in numerous instances, although skepticism is widespread as to the possibility of this phenomenon occurring in human beings. In a recent article on this subject by Gaylord and Clowes (*Surgery, Gynecology, and Obstetrics*, June, 1906), fourteen cases are mentioned which have been reported by various observers in recent years, and these are considered in connection with results obtained by the writers in animal experiments. For a number of years Gaylord has been a prominent worker in this field, and up to the present time over 3,500 mice have been employed in his laboratory for the experimental transplantation of a series of tumors. In one series, inoculated with a certain strain, 711 were accurately charted, and among these 101 cases of undoubted spontaneous recovery were noted. It seemed that the chances of spontaneous recovery in these mice diminished with increasing age and the dimensions reached by the tumor. The chances of recovery were apparently greater the slower the growth of the neoplasm, although there is some conflicting evidence on this point, and it is not fully accepted by the authors. An interesting fact, which was determined by these experiments, is that a mouse once recovered from carcinoma cannot be successfully reinoculated within a certain period, and from this it would appear that the animal under these conditions became endowed with a degree of resistance or immunity against cancer which it did not previously possess. Whatever the nature of this immunity may be, it does not appear to be cytolytic in action, "the histological picture indicating that the epithelial cells at the margin of the tumor are in some way robbed of their power of destructive proliferation, after which they undergo simple atrophy and gradual absorption by the surrounding connective tissue." Spontaneous cure of cancer in mice occurs, according to the estimate of these investigators, in about twenty-three per cent. of the cases. This frequency suggests to them that it may also be more frequent in human beings than is generally supposed. The interesting feature of their report, however, resides in the fact that we have here, apparently, sufficient warrant to continue the search for an anti-cancer serum, for the occurrence of a spontaneous recovery indicates that some force is present, or may be generated in the body, which is capable of terminating the disease.

Postoperative Parotitis.

In addition to the infectious types of parotitis, this gland may be the site of other inflammatory disturbances regarding whose origin we are still very much in the dark. Thus we meet with a variety of parotitis in women secondary to operations on the uterus or ovaries, which appears some six or seven days after a perfectly aseptic laparotomy without any apparent cause. The condition is not very common, but has usually been observed in the winter and may therefore, according to Morel (*Le Progrès Médical*, 1906, No. 13), be dependent upon the season. The affection is usually unilateral, and is most often seen on the right side, but it may also invade the other gland. Various theories have been proposed to account for this condition, the most likely of which assumes that some modification of the internal secretion of the ovaries by disease or trauma results in a diminution of the resisting powers of the salivary glands against infection. In the majority of cases the inflammatory symptoms subside without further complications, but sometimes suppuration results together with gangrene and sinus formation and the prognosis is always doubtful. The pus may burrow its way into the mediastinal space along the pharynx, or the auditory apparatus may become involved. Thrombosis of the large veins and the cerebral sinuses is also possible and has been noted together with severe venous and arterial hemorrhages. No means of directly preventing this unfortunate complication of abdominal operations has thus far been proposed, but in view of the fact above noted, that trauma of the ovaries may play some part in the production of the condition, it would seem wise to avoid as much as possible undue handling of these organs during the course of a laparotomy.

Slaughter-Houses in Philadelphia.—The Board of Health of Philadelphia announces that twenty slaughter-houses in that city, recently condemned as unsanitary, have closed permanently. Sixteen other establishments were improved by order of the board, and the owner of one slaughtering-house, who refused to obey the mandate to improve his plant, was ordered prosecuted.

News of the Week.

Cholera in the Philippines.—Dispatches from Manila announce that the cholera situation is steadily improving and that the number of new cases and of deaths is decreasing daily. Much satisfaction is expressed at the results obtained by the use of the vaccine prepared at the government laboratory, and it is stated that none of the natives of the infected districts who had been treated with the immunizing substance has contracted the disease. The Health Bureau supplies the vaccine free.

Malaria Among the Marines.—The United States cruiser *Columbia* recently sailed for Boston from Porto Rico with 300 marines on board, of whom 165 were suffering from malarial infection, contracted at Panama.

Typhoid Fever at Annapolis.—Three members of the new fourth class at the Naval Academy at Annapolis are down with typhoid fever which developed while they were on a practice cruise on the *Severn*, together with one hundred other plebes.

Typhus Fever in Philadelphia.—A case of typhus fever has been discovered in Philadelphia in the person of a young man recently arrived from Denmark. The patient was removed to the Municipal Hospital, where a fatal termination ensued. This is the first case of the disease in Philadelphia since 1888.

Chicago Public Health Matters.—According to the Bulletin of the Department of Health of the City of Chicago, during the week ended July 14, 498 deaths were reported from all causes, 27 more than for the preceding week, and 51 more than for the corresponding week of 1905. Acute intestinal diseases led the death causes with 68, followed by consumption with 58, heart disease with 40, violence, including suicide, and Bright's disease, each with 36, nervous diseases with 26, and cancer with 18.

A Chloroform Hallucination in Court.—A Parisian surgeon, who operated on a servant in the presence of her mistress, was accused by the servant of having kissed the mistress, the woman testifying that as she was recovering consciousness from the anesthetic she saw the act performed. The matter was brought up in a divorce suit, but as the result of the testimony of such prominent men as Brouardel and Debove, who pointed out the liability to sexual hallucinations of those under the influence of general anesthetics, the court rejected the evidence of the servant.

Maternity Statistics in Massachusetts.—In a bulletin issued by Chief Charles Felton Pidgin of the Massachusetts State Bureau of Statistics, it is stated that the United States census report, crediting Massachusetts with only 347 children to each 1,000 women, is misleading, since the Massachusetts Bureau considers that only married women should form the basis of computation. Estimated in this way, it appears that to every 1,000 mothers there are 3,958 children more than five years old. Foreign-born mothers have more children on the average than native mothers, but there have been twice as many deaths among children of foreign-born mothers.

To Test the Fuel Value of Alcohol.—An investigation into the possibilities of alcohol as a fuel for purposes of generating power is to be carried out by Prof. Charles E. Lucke, of Columbia University, for the United States Department of Agriculture. Some of the advantages attending the use of alcohol for this purpose are its lack of odor in combustion and the lessened danger from fire, since burning alcohol can be extinguished readily with water, while this is very difficult with gasoline and kerosene. The result of Prof. Lucke's work, together with a complete bibliography of the subject, will be issued by the Department of Agriculture in the form of a bulletin for free distribution on January 1, 1907.

To Enforce Pure Food Law.—The board appointed to formulate regulations for the enforcement of the recently enacted pure food law is to begin its work shortly. James L. Gerry, chief of the Customs Division of the Treasury, has been appointed as the representative of that department on the board. Dr. Harvey W. Wiley, chief chemist of the Agricultural Department, has been selected to represent that department, and Director North, of the Census Bureau, will represent the Department of Commerce and Labor.

Gift for Tuberculosis Sanatorium in Iowa.—Judge E. M. Carr of Manchester has offered to the State of Iowa a tract of forty acres of land, known as the "Devil's Backbone," if the authorities will use it for the erection of the State Hospital for Consumptives. The land has been used for years as a park, and is said to present some of the most beautiful scenery in the State. It consists of a high table land north of Manchester, around the rocky base of which runs the Maquoketa river.

Library of the University of Maryland School of Medicine.—Dr. Eugene F. Cordell, Professor of the History of Medicine and Librarian of the School of Medicine of the University of Maryland, announces the gift to the library of the Miltenberger collection of 949 volumes, bringing the total number of volumes in the library to 6,280. The library was founded in 1813.

A Fund for the New York Post-Graduate Medical School and Hospital.—A gift of $5,000 has been made to the New York Post-Graduate Medical School and Hospital by Mr. and Mrs. Edgar E. Brandon, of Oxford, Ohio, in memory of their son, William Templeton Brandon, to establish an obstetric ward in the Post-Graduate Hospital, where, in connection with scientific obstetrics, the complications and discomforts of pregnancy and of the post-partum period may be studied, and as far as possible alleviated.

Railroad Casualties.—In an accident bulletin issued on July 23 the Interstate Commerce Commission repeats its former opinion, that the block system is the best means for avoiding the occurrence of railroad accidents. The report covers the months of January, February, and March, 1906, and shows the total number of casualties to passengers and employees during this period to be 1,126 killed and 17,170 injured. This is an increase of 17 in killed and 52 in injured over those reported in the preceding three months. The number of passengers and employees killed in train accidents was 274, a decrease of 46. There were 1,921 collisions and 1,569 derailments, of which 289 collisions and 167 derailments affected passenger trains. The damage to cars, engines, and roadway by these accidents amounted to $2,924,785.

Danger in Cheap Bedding.—The public analyst of Hackney, England, has investigated the mode of manufacture of the cheap flock bedding sold in the poorer quarters of London, and has found that abundant opportunities for the spread of disease are furnished from this source. It is stated that filthy rags collected from dust heaps are shredded by machinery without any preliminary cleansing and are made into mattresses. One

gram of this flock yielded 7,590,000 colonies of bacteria, while only 6,400,000 were obtained from a like amount of sewage.

New Building of Children's Sanatorium Dedicated.—The new building of the Sanatorium for Hebrew Children at Rockaway Park was dedicated on July 22. The institution has 400 beds, and between 25,000 and 30,000 children from the tenements will be taken to the seashore during the season. A visiting staff of physicians has been appointed to aid the house staff in caring for the sick children, who are kept in the sanatorium until they have recovered. The sum of $1,600 was subscribed for purposes of maintenance.

A New Medical Association.—A conference was held at Kansas City, Mo., on July 16, of delegates from the States of Missouri, Kansas, Oklahoma, Arkansas and Texas, to consider the project of forming a new medical association to be called the Southwestern Medical Association. Five delegates were present from each State. One of the objects of the new organization is to secure greater uniformity in the registration laws.

Rutland County (Vt.) Medical and Surgical Society.—At the annual meeting of this society, held at Lake-View-in-the-Pines, Lake St. Catherine, on July 10, the following officers were elected: *President,* Dr. S. W. Hammond, Rutland; *Vice-President,* Dr. E. R. Clark, Castleton; *Treasurer,* Dr. J. H. Buffum, Wallingford; *Secretary,* Dr. C. F. Ball, Rutland.

Iowa and Illinois Central District Medical Association.—At the annual meeting of this association, held in Davenport, Ia., on July 12, officers were elected as follows: *President,* Dr. W. H. Ludwig, Rock Island; *Vice-President,* Dr. G. E. Decker, Davenport; *Secretary,* Dr. F. H. First, Rock Island; *Treasurer,* Dr. T. W. Kemmerer, Davenport.

The Maritime Medical Association.—At the meeting held at Charlottetown, P. E. I., on July 12, this association elected officers for the ensuing year as follows: *President,* Dr. A. B. Atherton, Fredericton; *Vice-Presidents,* Dr. T. D. Walker; Dr. M. A. Curry, Halifax; Dr. John Sutherland, Bedeque; *Secretary,* Dr. G. G. Melvin, St John; *Treasurer,* Dr. W. T. Farrish, Yarmouth.

Seaboard Air Line Surgeons.—The Association of Surgeons of the Seaboard Air Line, at the meeting held in Savannah, Ga., on July 14, elected the following officers: *President,* Dr. W. A. Monroe, Sanford, N. C.; *Vice-Presidents,* Dr. J. C. Wallace, Dade City, Fla.; Dr. H. M. Wilder, Charlotte, N. C.; Dr. E. H. Richardson, Atlanta; *Secretary and Treasurer,* Dr. J. W. Palmer, Alley, Ga. (re-elected).

Crawford County (Ill.) Medical Society.—At the twenty-sixth annual meeting of this society recently held at Robinson, under the presidency of Dr. Frank Dunham, the following officers were elected: *President,* Dr. L. R. Illyes, Heathsville; *Vice-President,* Dr. J. M. Mitchell, Oblong; *Secretary,* Dr. H. N. Rafferty, Robinson (re-elected); *Treasurer,* Dr. Frank Dunham, Robinson.

Death of Dr. Brouardel.—Dr. Paul Brouardel of Paris died on July 23, at the age of sixty-nine years. He was well known as a practitioner, writer on medical subjects, and medico-legal expert. For many years he was president of the consulting committee of the Department of Public Health, and he was made commander in the Legion of Honor in 1885. His death is ascribed to a chilling received some weeks ago while performing an autopsy in the morgue.

Obituary Notes.—Dr. Sophronia Fletcher of Cambridge, Mass., said to be the oldest woman physician in the country, died of pneumonia on July 19, at the age of ninety-nine years. She was in her usual health until a few days before her death. Dr. Fletcher was the first woman instructor at Mt. Holyoke College, where she held the chair of physiology over fifty years ago.

Dr. Rorert H. Theyson of this city died on July 18 of peritonitis in St. Luke's Hospital at the age of fifty years. He was a graduate of the University Medical College in 1890.

Dr. Edward G. Tufts of this city died suddenly on July 21 at the age of fifty-five years, He was born in this city, and was graduated from the University Medical College in 1881.

Dr. Walter B. Odiorne of Cambridge, Mass., died on July 14 at the age of thirty-three years. He was graduated from Harvard College in 1895, and received his medical degree from the Harvard Medical School three years later.

Dr. Elmer Beecher of Burlington, Vt., died on July 16, after a short illness, at the age of ninety-six years. He was born in Hinesburgh, and received his medical degree from the Castleton Medical School. He was State Senator from Chittenden County in 1860.

Dr. Joseph B. Hosken of Grand Rapids, Mich., died on July 10 at the age of fifty-five years. Dr. Hosken was born in Coburg, Ont., and was graduated from the University of Michigan in the class of 1875. He had practised in Grand Rapids since the year after his graduation.

Dr. E. G. Cawley of Haverhill, Mass., died on July 10. Dr. Cawley was born in Sanbornton, N.H., and received his medical degree from the Baltimore Medical School in 1900. He had practiced in Haverhill since 1902.

Dr. Robert H. Alison died suddenly of apoplexy at Ardmore, Pa., on July 16 at the age of fifty-nine years. He was born in Western Pennsylvania, and was graduated from Yale College in 1867, and from the Medical Department of the University of Pennsylvania in the class of 1869. In the early part of his career he was for a short time Port Physician for the city of Philadelphia. He was one of the physicians to Bryn Mawr Hospital.

Dr. David R. Streets died suddenly at Bridgeton, N. J., on July 15 at the age of fifty years. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1880 and from Hahnemann Medical College in the class of 1880.

Correspondence.

THE D'ARSONVAL AND OTHER HIGH-FREQUENCY CURRENTS, WHAT THEY WILL DO.

To the Editor of the Medical Record:

Sir:—Doctor Piffard's recent very learned article on this subject in the *New York Medical Journal* is bound to attract widespread attention. In it he shows his mastery of what may be called the physics of electricity, and also gives the result of his clinical experience with the application of this particular current. His article is headed "The D'Arsonval and Other High-Frequency Currents, What They Are and What They Will Do." In my own heading I leave out "What They Are," because I know not. I have them bottled up in my office and am daily using them in the effort to discover. The electrician who established them for me gave as his own clinical experience that there were "lots of things nobody understands in this machine," and I agree with him perfectly.

There is one point, however, in which my own expe-

rience may supplement that of Dr. Pillard. He says, "Localized pruritus, especially of the genital regions, has ceased to trouble sometimes after a single application." Of course I have no doubt of the accuracy of his statement, but by far the most extensive, serious, and intractable case of pruritus ani treated by me in the last two years seemed to have been in great measure caused by this method of treatment. In the beginning when seen by a prominent dermatologist it was a simple neuritis without changes in the skin. A few weeks later, when seen by me after an intervening course of treatment with the high-frequency current in the hands of a third party, it was an intense eczema of the entire genital region; and this change was confirmed by the dermatologist referred to, and the relation between treatment and effect seemed obvious. The suffering was finally relieved and the lady cured only by free applications of the actual cautery.

Such a case proves nothing in the absence of more precise details as to the way the current was applied and all other particulars. It is given only as a personal observation and a caution.

CHARLES B. KELSEY, M.D.

44 EAST TWENTY-NINTH STREET, NEW YORK.

OUR LONDON LETTER.

(From Our Special Correspondent.)

THE "CHRISTIAN SCIENCE" CASE—APPENDICITIS AND GANGRENE—NASAL SPURS AND DEVIATIONS—UNIVERSITY AND COLLEGE—PRIZES—NATIONAL TEACHING OF HYGIENE—COUNTY COUNCIL'S PROPOSALS RE LUNACY AND FOOD INSPECTION—OBITUARY, GARCIA, RAMSDEN.

LONDON, July 6, 1906.

THE "Christian Science" case has ended in an unusual way, leaving everything unsettled. The trial of the accused for manslaughter by neglect, he being a qualified practitioner who had left the profession to study Mrs. Eddy's notions, lasted from June 27 to 30. The judge charged the jury that they were not trying "Christian Science." If a man stood in the relationship of medical attendant, he was bound to bring to the case care and proper skill. If the patient preferred this treatment and would have no other, it was not because his death resulted from his own obstinacy that someone else was responsible. The jury could not agree, and at last were dismissed and the prisoner released on his own recognizance. A new trial had therefore to be arranged, but on Monday the judge told the counsel in open court that in his opinion a conviction would be undesirable, the evidence for the prosecution not being sufficient, in his opinion, to bring home guilt. There are some curious points in the defense put forward. Counsel said the accused was a doctor in name only, as he had abandoned medicine and visited deceased only as a friend. To explain the fact that the hypodermic syringe and tablets of morphine and strychnine were in accused's possession when arrested, he said defendant was a victim to the drug habit and had been cured by Christian Science, and of course counsel attacked the medical witnesses for the prosecution in the usual shameless way. The accused himself, on examination, said deceased died of exhaustion, and that as soon as he gave up hope and Christian Science he died. He believed, he said in reply to the judge, that Christian Science cures all ailments, also all poisons, even snake-bite. Asked if it cured indigestion, he said "Yes," which produced laughter, as his first explanation of carrying drugs was that he suffered from it.

Many other statements were made in these lengthy proceedings, but though the exposure of fallacies may be served, it is clear that no light has been shed on the law concerning the relationship of doctors and patients.

At the Medico-Chirurgical Society on June 26th inst., Mr. J. D. Malcolm endeavored to show that in many cases a gangrenous patch in the vermiform appendix is the starting point of disease and might be independent of appendicitis, though often associated with it. He submitted cases and statistics showing that nearly one-third had perforations of the wall without any attempt to localize the mischief by adhesions. When inflammation began in the mucous membrane, he considered it safe to watch the case, but when the initial lesion was gangrene operation could not be too early, and so, too, in gangrene complicating appendicitis.

Mr. A. Doran mentioned a case in which collections of fat in the mesoappendix set up gangrene.

Mr. C. B. Lockwood said at least 85 per cent. or cases of appendicitis began in the mucous membrane. It was probable that bacteria found their way through superficial ulcerations, for a great deal of evidence would be required to negative the presence of ulceration. He did not admit spontaneous gangrene. The indications of appendicitis in the early stages were rising pulse, temperature, and leucocytosis.

Mr. A. Baldwin compared gangrene of the appendix with gangrene of both ends of intestine after end-to-end anastomosis, and considered bacteria to be the cause of both.

A paper by Dr. St. Clair Thomson was then read, describing his operation for submucous excision of nasal spurs and deviations. The mucous membrane was preserved intact, but the bone and cartilage effectually dealt with. The results in thirty cases were completely satisfactory.

At the prize giving of University College—the last prior to incorporation with the University of London—there was a pleasing ceremony in the presentation to the Council of the portrait of Dr. Carey Foster, as a memorial of his life work at the college, where he had been a student and afterward professor for over thirty years. In 1898 he became principal, an office which will lapse on the incorporation. A replica was presented for Mrs. Foster. In returning thanks, Dr. Carey expressed his belief that the incorporation would be a great step and improve the resources of the University, which have hitherto been dispensed in separate bodies. These had done excellent work, he declared, but divided they did not impress the public in a way to attract support. By union the University would become a great seat of learning, where the teachers would be drawn together. The prizes were then distributed by Dr. Carey Foster.

At King's College, Sir A. Rücker, principal of the University, distributed the prizes and then addressed the students. He said the bonds between the college and university were being drawn closer. King's was to be congratulated on what it had already done, and the throwing open of its laboratories to the students of the great medical schools was having a good effect; those students who came from other schools were members of the University. They would have a double loyalty to their College and to their University. The same state of things existed at Oxford and Cambridge, and the two loyalties were not incompatible.

From another speech on this occasion I learn that the negotiations between this College and the University are approaching a point where we may receive a definite statement. King's desires to incorporate as completely as University College, but there are obligations in its trust for which some provision must be made. King's is, in fact, a denominational college. University recognizes no sect or denomination.

At Guy's College, Sir Cameron Gull distributed the prizes and said his only claim to such a privilege was heredity, for his father took the deepest interest in Guy's, and anything in his own power to further its interests he would do. He reminded the students that they must be prepared for positions of great responsibility and to face, perhaps unaided, most difficult problems. So it was necessary that a school should bring up its students to be fully qualified, and they must keep abreast with the rapid advance of medical science. He wondered the public took so little interest in medical schools. Perhaps it was through that noisy section which tried to persuade them that vivisection was an evil. For his part, he believed vivisection was absolutely essential to full training in medical science. Guy's could speak freely on this matter, for the governors had never helped the school with hospital funds. But what would the hospital be without the staff, and where would they get the staff if there were no medical schools? If the public only realized the needs of the school they would be more generous.

Mr. Pearce Gould presided over a conference held last week on the national teaching of hygiene and temperance. He commented on the neglect in education of the vital subject of taking care of the body. The conference advocated the provision of competent teachers, who would travel through the country and teach the principles of hygiene in the elementary and secondary schools. Professor Sims Woodhead, vice-president, said the work of the association had been carried on deliberately and with most careful consideration. They wanted £450 in the first instance for the training of teachers, and he hoped those present would give not only moral but pecuniary support. Other speakers addressed the meeting on the effects of alcohol, and urged the importance of hygiene. One rather blamed medical men for recommending nursing mothers to keep up their strength by drinking stout—a fallacy which partially accounted for the increase of female inebriety.

The County Council, as I foreshadowed, has decided

to reintroduce the bill giving it power to establish and maintain receiving houses for lunatics. It was stated that in New York the experience was favorable, and had been adopted on the recommendation of a delegation to this country five or six years ago. Thus it seemed that while this Council was discussing the plan, New York had put it in practice. The Council also, on the recommendation of the Health Committee, decided to apply for authority to deal with the milk supply within the county. It was proposed to take samples at railway stations and elsewhere, and to deal with such as were unfit for consumption. It is also desired to compel dairymen to supply lists of their customers and of the sources from which they obtain their milk. There was some opposition to this proceeding, and it seems doubtful whether the new free trade government will permit so strong a measure of interference with free trade, even for the sake of securing wholesome food for the people.

The death of Manuel Garcia, which took place on Sunday in his sleep, will recall to you the manner in which we celebrated his one hundredth birthday on March 17, 1905. Eminent members of the musical and medical world then combined to render him their respects, and the King, his own sovereign, the King of Spain, and the German Emperor conferred decorations. The story of his invention of the laryngoscope need not be retold to-day; it will remain a part of the history of the instrument. His method of teaching and his views on voice training are as well known to the musical world. He was twice married, the second time to an English lady, who survives him. His son, Gustave Garcia, continues to represent his father's methods, as expounded in the "Traité Complet de l'Art du Chant."

Dr. Wm. B. Ramsden, lecturer on chemistry at Manchester University, when about to commence a lecture in the public health laboratory on Friday last, suddenly lost consciousness, and on being examined was found to be dead. He was a brilliant student of Owen's College, and after graduating was appointed on the staff of lecturers and was generally regarded as a most promising teacher. He has passed away at the early age of twenty-nine.

OUR PARIS LETTER.

(From Our Special Correspondent.)

THE DIAGNOSIS OF APPENDICITIS—THE SERUM TREATMENT OF TUBERCULOSIS—DEATH OF DR. ALBERT JOSIAS.

PARIS, July 1, 1906.

AT the Académie de Médecine several long and interesting discussions have been held on the question of false appendicitis. The matter was first brought up by Dieulafoy, who presented a communication in which he took the stand that many people suffering simply from colitis were operated on for appendicitis which did not exist. The author, although an advocate of the surgical treatment of appendicitis, believed that many operations were performed unnecessarily, owing to diagnostic errors. In support of this view he referred to eleven cases he had observed, which led to the following conclusions: There are patients suffering from mucomembranous enterocolitis, of which the typhlitis is the most conspicuous feature. In such cases the pain is most intense in the right iliac fossa, and then, owing to the common belief that appendicitis is a frequent consequence of enterocolitis, the typhlitis is overlooked and an operation is done for an inflammation of the appendix which does not exist. The appendix does not take part in these painful seizures in the right iliac fossa, which are caused by mucomembranous typhlitis and not by appendicitis. Besides, the removal of the appendix does not relieve the typhlocolitis, and the patients continue to have the same painful attacks as before. It therefore behooves us to check this rising flood of unnecessary operations by cultivating the art of more accurate clinical diagnosis.

Reclus disputed point by point the observations made by Dieulafoy. He first stated that little weight could be attached to the observations presented by this speaker, who had omitted, he said, to report the results of microscopical examination of his cases. As for the question of the relationship between appendicitis and typhlocolitis, it did not seem settled to the author, and he was unable to understand the assertion of Dieulafoy in this connection. To the eleven cases of Dieulafoy he opposed fourteen, in all of which there had been undoubted enterocolitis and in all of which also the diagnosis of appendicitis was verified by the operation and characterized by gross lesions, which rendered the use of the microscope unnecessary. It was not, he said, to cure typhlocolitis that the appendix was removed, as Dieulafoy seemed to believe, but in order to relieve patients suffering from appendicitis from the dangers of this condition. If the typhlocolitis were also cured, so much the better, but it was not this that gave the indication for the operation. Nevertheless, he declared that he agreed with Dieulafoy in regard to the difficulties sometimes presented in the diagnosis of chronic appendicitis, but he considered that it was not without danger to denounce in public "these errors of diagnosis and mistaken operations."

Richelot in his turn protested against the assertions of Dieulafoy, although he admitted that in recent years there had been some excess in operating. Le Dentu also considered that Dieulafoy's opinion was exaggerated, and stated that the coexistence of appendicitis and typhlocolitis was by no means the rarity that the former speaker had alleged. He had seen numerous cases of this sort, and it was very difficult under these conditions to determine which had been the original lesion, the appendicitis or the colitis, but he was able to refer to several instances in which appendectomy brought about a cure of the enterocolitis. As for the histological aspects of the question, evidently it was not right to assert that an appendix found healthy or almost so at an interval operation had always been so. There was also one region which always escaped observation, that is, the root of the appendix, or Gerlach's valve, and it was only fair to think that in many cases the inflammatory process might be restricted to this district. The diagnosis of typhlocolitis and of appendicitis was difficult, especially in chronic cases, but when the pain was very limited appendicitis was more probable. Even though present, however, it did not necessarily indicate an operation.

Reynier first pointed out the deceptive nature of McBurney's point, saying that typhlocolitis, appendicitis, salpingitis, etc., might all manifest themselves in the same way. He further stated that mucomembranous enterocolitis might be of appendicular origin, and that appendectomy might cure the condition, though it did not always do so.

Dieulafoy in replying stated that he had not intended to discredit surgery, but he had thought it was his duty to come forward, on account of the number of people he had seen operated on for appendicitis when they were suffering only from mucomembranous typhlocolitis, and because he had seen operative errors sheltered behind falses diagnoses. He held to his views, and to the surgeons who wished to consider the relationship between appendicitis and typhlocolitis he recommended the statistics of Potain. As for the cases he had cited, he considered them irrefutable; in all of them the histological examination had been made, and nothing had been kept back. On the other hand, the attacks of typhlocolitis had reappeared in the patients, and it was evident that what had been considered appendicitis had really been typhlocolitis. Errors of this sort were frequent.

Reclus reaffirmed his arguments, and said that in spite of Potain's statistics the coexistence of appendicitis and mucomembranous enterocolitis could not be denied.

Dieulafoy took up the discussion again to announce to the Académie that Dr. Duret, professor of surgery of the Faculté de Lille, had commissioned him to present a communication concerning the question then under consideration. Duret insisted that typhlocolitis was often mistaken for appendicitis, and agreed with Dieulafoy in saying that many people were unnecessarily subjected to appendectomy. The speaker closed by saying that the sole object of his communication had been to beg in the name of careful diagnosis that more pains should be taken in order to avoid operative errors.

The serum treatment of tuberculosis has been occupying the attention of the Académie des Sciences. We shall not report all of the papers relative to experimental serotherapy presented by Calmette, Guérin, Roux, Vallée or Arloing. Considerable interest attaches, however, to a communication presented by Lannelongue, who, together with Achard and Gaillard, has been experimenting in this field for the past seven years. At this time, when in Germany Behring is carrying out researches which are prematurely being considered as conclusive, it is only fair to point out that French science is not behindhand, and that though they may be less noisily heralded, the observations of French workers are not lacking in importance. Lannelongue, for example, has experimented on guinea pigs with a toxin obtained from human bacilli. The animals infected in this way were divided into two lots, a certain number of

controls being set aside, and the others were subjected to the action of sera obtained from the horse and from the donkey. At the end of 371 days 90 to 96 per cent. of the controls had succumbed, whereas of the animals treated with the horse serum there was a mortality of only 60 per cent., and of those treated with donkey serum a mortality of only 40 per cent. Several experiments already made with the donkey serum in dealing with human tuberculosis have shown that it does not cause febrile reaction and that it is well borne. The author described the case of a young girl suffering from tuberculous laryngitis, whose condition rapidly improved under the use of the serum.

The medical corps of the hospitals of Paris has suffered the loss of one of its most esteemed members, Dr. Albert Josias, who has died at the early age of fifty-three years. He was a member of the Académie de Médecine, an officer of the Légion d'Honneur, physician to the Hôpital Bretonneau, sanitary inspector of the City of Paris, and member of the superior board of health of the Department of the Seine. He was the author of numerous works relating principally to matters of sanitation and forensic medicine. He also had published important discussions of tuberculosis in children and the treatment of diphtheria. In 1896 he published a book on the therapeutics of childhood, and he was a collaborator on the "Traité de Thérapeutique," edited by Albert Robin.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

THE CULION LEPER COLONY—MANUAL LABOR FOR LEPERS—TRACING AN OUTBREAK OF CHOLERA.

MANILA, May 31, 1906.

THE construction of the Culion Leper Colony at its present location was begun in 1904, and it has now advanced to a stage where there are a sufficient number of buildings completed to provide accommodation for 600 lepers. Three hundred and sixty-five were removed from the island of Cebú and landed at Culion on May 27, 1906, and the remainder will be sent as soon as practicable. It is the intention to make the Culion Colony a model institution. It is already the only model and up-to-date town in the Philippine Islands, in that it is supplied with a proper water and sewer system. The water is obtained from a spring located near the sea level, and then pumped into a reservoir, the bottom of which is at an elevation of 260 feet above the sea, and about 130 feet above the higher parts of the leper town. The reservoir has a capacity of 80,000 gallons. The water is conducted by pipes to the Colony, and then through the various streets. An ample number of fire-plugs have been installed, and a sufficient number of bath-houses, closets, and wash-places for 800 lepers are already provided.

The colony is situated on a small hill, which slopes on three sides toward the sea, thus making the drainage a comparatively simple matter. In order to guard against the pollution of the bay, all sewers are conducted to a modern septic tank, the overflow from which is well filtered before it is permitted to flow into the sea. The Colony, at the present time, consists of about 100 houses constructed of nipa and bamboo, in the style in which the natives are accustomed to build houses. The average capacity of a house is from six to eight lepers. It is the intention to do all the cooking at one place, and for this purpose a large mess hall, in which 300 persons may be seated at one time, has been provided. By having only one kitchen greater economy can be practised, and the cost of subsistence reduced to a minimum.

It is hoped that the Colony can be made self-supporting to a large extent, by inducing the lepers to catch fish, hunt the wild hogs, deer, and other game which abounds on the island. The proposition of having the lepers act as herdsmen in raising cattle for the market is now receiving consideration. This latter occupation would require very little manual labor, and it is thought that there would be but slight objection to such cattle being sold in the open market, provided they were slaughtered at once.

Of the lepers found in the Philippine leper institutions, not more than one-third are capable of any manual labor, and the efficiency of this latter number is seriously impaired owing to the absence of fingers and toes, various contractions of the muscles, and the atrophy of the bones, etc., so that about three or four of these would be required to perform the labor of which the average sound laborer is capable. It will be seen, then, that after the lepers who are capable of doing work perform the necessary tasks incident to providing for themselves, as, for instance, cooking food, waiting on table, sweeping streets, making minor repairs to houses, fire drill, etc., etc., that very little surplus labor will be left which can be devoted to their own support.

In order to make the life of the lepers as pleasant as possible, a large amusement hall has been provided, where they can have theatricals and other diversions. A sufficient number of band instruments for a band of thirty pieces has been purchased for them. It is the intention to permit them to organize a municipality, for which they may elect their own officers, appoint their own police force, etc., etc. It is also intended to give them as much liberty of movement as possible. This is feasible because the entire island has been set aside for lepers, and escape from it would be difficult. At any rate, it is presumed that the inhabitants of the nearby islands will not welcome them to their shores, and if any lepers should land they would probably return them to the Colony.

In view of the fact that births have been extremely rare in the leper institutions of the islands, it has been decided not to separate the sexes, at least for the present.

The chain of evidence which has been collected for the purpose of showing the origin of the recent outbreak of cholera in Manila is now more or less complete. It appears that at the Manila and Dagupan railway station a pail system has been maintained, and the fecal contents of the pails dumped into a nearby canal. It is presumed that an individual with cholera organisms in his stool arrived at the station from one of the infected provinces, and used one of these pails. After the outbreak of the cholera commenced it was soon noticed that practically all the cases occurred among persons who lived on the streets which ran along either side of the canal. A bacteriological examination of the water was immediately made, the result of which showed that cholera organisms were undoubtedly present. The water from a number of other canals has been examined, but with negative results. Immediately afterward a heavy rain occurred, which thoroughly flushed the infected canal, and since that time the cholera has ceased, with the exception of an occasional isolated case that is attributed to eating infected vegetables that are grown in the vicinity of the canal and probably have been sprinkled with its water.

Progress of Medical Science.

Boston Medical and Surgical Journal, July 19, 1906.

Therapeutics Based on Pathological Physiology.—R. C. Cabot offers the following conclusions: (1) Treatment based on pathological physiology is not the best type of therapeutics yet worked out; neither is it the worst. It occupies a postiion intermediate in value and efficiency between etiological treatment (or that which removes the cause of disease) and symptomatic treatment, which simply smothers a symptom. (2) It is based on theories of the nature and trend of the body's reaction against the *materies morbi*, theories which, like all valuable hypotheses, must be constantly and empirically verified. (3) Empiricism is not a type of treatment, but an essential element in all treatment. Nevertheless: (4) Theory is invaluable because it furnishes the motive power of most scientific progress; empirical verification guides but does not initiate this progress. (5) Treatment that aims to remove the cause of disease should neglect very largely the individual factors in the case, but treatment based on pathological physiology can be effective only by ascertaining and respecting the physical and psychical peculiarities of each individual and the unique relations in which he stands to his family, his work, his education, his place of residence, and many other aspects of his environment. (6) Etiological or symptomatic treatment must first ascertain at what spot in the organism the trouble resides. To that spot it then directs its energies. But treatment based on the individual's manner of reacting to the disease must study the whole individual so far as it can discover him. *Journal of the American Medical Association, July 21, 1906.*

Anastomosis of the Vas Deferens.—G. F. Lydston says that in a certain, as yet undetermined, number of cases it is possible to reestablish the continuity of the vas deferens after a previous vasectomy has been performed. The chief indication for this is in cases of accidental severance of the vas, but in case of double resection, followed at a longer or shorter period by anastomosis, there are two chances of restoring fertility. One

or the other vas is liable to regain patency. The time that should elapse between the vasectomy and the anastomosis varies, according to the improvement in the condition for which the vasectomy was performed. The method of anastomosis consists in excising the nodule at the point of resection, bringing the two ends together and uniting them after having inserted into their lumen a strand of large-sized silk-worm gut, the proximal end of which is passed out by the threaded needle about an inch and a quarter above the anastomosis and out through a puncture in the skin a little above the upper angle of the wound. The object of this silk-worm gut thread is to preserve the continuity of the lumen, and it should be removed at the end of a week. A portion of the free edge of the fascia, which was divided to expose the parts, is wrapped closely around the vas so as to close it in completely. The fascia is closed with fine catgut and the edges of the scrotal wound brought together with fine silkworm gut or horsehair.

The Poison of the Meningococcus.—A. P. Ohlmacher, by experiments on horses, has demonstrated the existence of a powerful poison from the meningococcus, the effects of which are best manifested by intravenous injections of a filtrate through paper of a tricresolized extract of a three to six-weeks' culture on a glucose-chalk-bouillon. The symptoms produced are restlessness, increase of pulse, temperature, and respiration, profuse perspiration, together with the special nervous symptoms of progressive asthenia, tremors, clonic convulsions and transient opisthotonus, excessive irritability, spasms being caused by noises or unexpected touch, and finally death from exhaustion. The nervous manifestations were best produced by the special culture product above mentioned, but ordinary broth cultures were also toxic; sufficient subcutaneous doses of the special extract, besides causing fever and extensive local swelling, also gave rise to the nervous symptoms. The poisonous effect was absent when the fluid was filtered through unglazed porcelain bougies or balloons, but was present and active in the product of filtration through Berkefeld candles or paper.

Radium in Surgery.—R. Abbe has employed very powerful radium applications in 127 cases, covering a large number of conditions. The greatest interest is in the morbid growths, such as lupus, epithelioma, sarcoma, etc., and he remarks here that in every case in which he has laid a radium tube on a wart the growth has rapidly disappeared by retrograde degeneration of the cells composing it. In thirty-five cases of lupus and epithelioma all have shown improvement, and twenty patients have recovered, at least for the time. In the graver cases of cancer the results are less favorable. Of eleven operable cases tested, six patients were subsequently operated on. In the other five the operation was deferred on account of improvement. He thinks that possibly with the use of radium in some other way than with the thin glass tubes employed, better results may be obtained. In one type of grave cancer, mammary cirrhus, the agent seemed to promise good results. In three cases, in which the breast was subsequently amputated, microscopic examinations showed characteristic retrograde changes, which may explain the improvement in four others similarly treated. In sarcoma the results were rather brilliant and several cases are detailed. In two cases of spindle-celled sarcoma there was only seeming arrest, but no retrograde changes so far as observed. In overdosage, or with too long exposures, radium rays are destructive rather than alterative, and he has seen toxic conditions aroused by overzealous methods. Experience in goiter encourages further experiment, but not positive claims as to specific benefits. In pigmented moles removal by dry necrosis can be produced, and results possibly better than by the other methods. He sums up his conclusions as follows: 1. Radium action resembles that of Roentgen rays. 2. It differs specifically, and will cure some cases promptly which resist the latter. 3. It is applicable to the interior cavities of nose and mouth inaccessible to the Roentgen ray. 4. It is curative in most superficial epithelial cancers and lupus. 5. It has failed of curative action as yet in forty test cases of grave internal cancers. 6. It promises interesting results in other surgical conditions under study.

Uncinariasis in Mississippi.—C. C. Bass has obtained a record of 206 positive cases of uncinariasis in Mississippi, and of 30 in which the diagnosis was not so positive. These cases altogether represented 23 of the 76 counties of the State, and in 12 more ground itch was reported. He believes that the State is very widely affected, and suggests a legislative inquiry as to the prevalence of the disease and the best means to disseminate knowledge in regard to it, so as to check its ravages. He also recommends a method of finding the ova for diagnosis based on the fact that they will float on a solution in which the balance of the feces will precipitate. Without giving exact figures of specific gravity or saying what is absolutely the best solution, he claims that for practical work nine-tenths of a saturated solution of sodium chloride will suffice. He hopes to work out the technic more fully and to give results in a future publication. The article is accompanied by several tables and charts.

New York Medical Journal, July 14, 1906.

Death from Suppurating Tonsil.—V. Kenerson reports one case of fatal sepsis following a tonsillar suppuration. The patient was a woman of thirty-three years, with the typical local appearance in the mouth of a left-side quinsy. Foul pus was evacuated, but reaccumulated in twenty-four hours and was again evacuated. For the next two days masses of sloughing tissue came away and she began to have cyanosis and dyspnea. Again pus was evacuated, causing her to rally somewhat, but she again became cyanotic with so much dyspnea that a tracheotomy was decided on, but before it could be done she was unconscious. The tube was inserted, however, and she was kept alive for some hours, but finally died from the general sepsis.

Deformities of the Trunk in Children.—L. C. Ager divides these deformities into the following classes: (1) Fractures of the ribs, vertebræ, or pelvis, generally evident from the history and by direct examination. (2) Deformities due to inflammatory exudates and abscesses. This class includes inflammation of the various glandular structures, the rare external observations of internal pus showing as from the pleural cavity, liver and psoas disease, fracture calluses and periostitis of the ribs following typhoid. (3) Hernial. (4) Abnormal size, shape, or position of any internal organ may cause an external protuberance. In the chest we find precordial bulging referable to advanced cardiac hypertrophy; in the abdomen we may not always be sure of the exact cause, as many organs are there situated, which may give like symptoms. (5) Large amounts of fluids in the various body sacs (pleura, pericardium, abdomen) may give external manifestations similar to those classified under (4). The author discusses the various classifications above outlined, giving particular attention to spinal and chest deformities. Nothing new is brought forward.

Differential Diagnosis and Clinical Significance of Peritonitis.—G. P. La Roque discusses this question from the academic standpoint, enumerating as diagnostic symptoms the association of pain, tenderness, muscular rigidity, constipation, vomiting, and, as a rule, disturbances in circulation and temperature. In the diffuse fulminating form of peritonitis, we have a sudden overwhelming toxin infection resulting in diffuse peritoneal irritation, reflex shock and profound sepsis. In this form, the earliest symptoms are referable to the irritative factor, viz., pain, tenderness, rigid, spasmodic, abdominal, and diaphragmatic immobility, absent peristalsis with absolute constipation and general tympany, persistent, easy, regurgitant vomiting, and rapid, running, wiry pulse. The onset of shock may obscure the pain and tenderness, still more accelerate and enfeeble the pulse, and rarely counteract the development of fever. Extreme collapse and prolonged, excessive nerve irritation may produce final paralysis of sensation and muscular contraction, with disappearance of pain, tenderness, and spasmodic rigidity. The vomiting, constipation, tympany, and distention rigidity generally persist and are progressive in intensity. In many cases of puerperal peritonitis and pneumococcic infection in children, constipation may be replaced by exhausting septic diarrhea. Leucocytosis, except at the outset, is valueless. Fever may be wanting. The author enumerates the various retro- and infraperitoneal lesions which may confuse the diagnosis, and points out some of the characteristic features of each. This part of the paper covers only the familiar ground of any good surgical treatise and does not need reproduction here. Concerning subdiaphragmatic abscess, the author notes as its most common cause perforation of the posterior wall of the stomach or duodenum. Other possible causes are abscess of the liver, appendicitis, splenitis, pancreatitis, and abscess, externally, but rarely in the pleura. The cardinal symptoms are those of localized peritoneal abscess formation associated with marked respiratory disturbance. On account of its subcostal location a tumor can only exceptionally be discovered. The belly and particularly the hypochondrium is rigid, tender, and distended. The costal arch is markedly tense and instinctively immobile. Hiccough may occur but is in no way characteristic. Constitutional signs of hectic fever are severe. The diaphragm is pushed upward and the spleen or liver (depending on the loca-

tion of the abscess) is in rare cases depressed. Since the great majority of subdiaphragmatic abscesses result from gastrointestinal perforation, they, as a rule, contain gas. Amphoric sounds may be elicited by auscultation and percussion. Differential diagnosis must be made from hydropneumothorax.

The Lancet, July 7, 1906.

A Means of Checking the Spread of "Sleeping Sickness."—According to J. L. Todd, this malady, which is essentially a human trypanosomiasis, is widely spread over Africa and is spreading rapidly. This contention is supported by the study of certain maps, which the author presents in his paper. He believes that each of the eight varieties of the tsetse-flies ought to be regarded as a possible carrier of the disease, that is, of the *Trypanosoma gambiense*. The epidemiology of the disease shows that its natural spread is slow, but that it may be carried rapidly by human intercourse along the recognized routes of travel. The measures recommended for preventing the spread of the disease are: (1) the establishment of medical posts of inspection along the trade routes leading from infected to uninfected districts; and (2) the removal of infected persons from posts in uninfected districts to places already infected. If success is to be obtained the application of these measures must be thorough. Cases of trypanosomiasis, though apparently healthy, may be detected by their enlarged glands, and we may expect to check the advance of the malady by the serious application of quarantine measures dependent for their efficiency upon cervical gland palpation.

A Note on the Action of the Serum of Various Mammals on the Bacillus Pestis.—G. Lamb and W. H. Forster detail the results of their experiments with the serum of man and the following animals: Monkey, horse, ox, sheep, dog, goat, rabbit, guinea-pig and rat. Technic is described in full. From their tabulated results no evidence of bactericidal power can be discovered. The authors state that, on the contrary, it was found that the serum of all the animals examined proved to be as good a medium for the growth of *Bacillus pestis* as ordinary nutrient broth. Four observations were made with the serum of each animal, but as the result in all cases was consistently negative, so far as bactericidal action was concerned, only one experiment is recorded for each animal. From these experiments it would seem that normal mammalian serum is devoid of any bactericidal action on *Bacillus pestis*. The explanation of the immunity enjoyed under natural and artificial conditions of infection by some members of the order of mammalia must be sought in some other direction.

Motor-Driver's Spine.—A question mark follows the title of W. J. Burroughs' paper, making it appear that he himself is a little doubtful whether or not he has discovered a new occupation neurosis. The salient features in the case described by him are as follows: His patient was a healthy man of thirty-four years, temperate and without any evidences of syphilis. After an unusually hard day in driving a heavy motor-car, which required repairs on several occasions during the journey, he complained of acute pain in the right hip, dull ache across the loins, and inability to move the right leg. Pulse, respiration, and temperature were normal. Eyes were normal. Tenderness on pressure was felt to the right of the third and fourth lumbar spines, extending outward about six inches over an area about three inches wide. The whole of the right leg was in a state of spastic rigidity. No bladder or rectal symptoms. The patellar reflex in both legs was exaggerated but much more markedly on the right side, and on both its production caused shooting pain referred to the lumbar region. The skin of the whole of the right leg was hyperesthetic, this state being more pronounced upon the inner surface of the limb. The drawing of the pulp of the forefingers slowly up the sole of the right foot caused great pain, and the same action conducted quickly made the patient cry out loudly and draw up the foot, an action he was quite unable to accomplish voluntarily. Ankle clonus could not be obtained. The condition of the left leg apart from the increased knee-jerk was practically normal. On the following day the pain in the hip was slightly less, though its presence had given the patient a bad night. The muscular rigidity had considerably decreased, but girdle pain coming on at intervals and starting at a spot corresponding to the third and fourth lumbar spines, was complained of. The patellar reflexes were almost unobtainable, and the sensation of the right leg was greatly diminished. The pulse, the respiration, and the temperature were normal. On the next day the knee-jerks of both sides were absent. The rigidity had disappeared, and complete anesthesia of the whole of the right leg with a diminution of sensibility to heat and to cold existed, sensation in the left leg remaining unimpaired. From this time on there was a gradual improvement, and in about three weeks from the appearance of his initial symptoms he was able to be up and out of doors. The author's diagnosis was a "localized myelitis." He calls attention to the case because, in his own mind, there seems little reason to doubt that the cause was intimately connected with the conditions under which a comparatively new occupation is conducted, and although he is unprepared to say whether the pathological state produced was the direct outcome of the constant jarring to which a driver of one of these vehicles is exposed, or to the excessive muscular effort required of the patient on the particular day on which he developed his malady, the fact of his illness remains, and it would be interesting to learn if similar cases have come within the experience of others.

British Medical Journal, July 7, 1906.

Cancer.—Sir S. Wilks discusses some of the present-day views on the nature of cancer as learned during the last half-century by the gradual perfecting of the microscope. Years ago the author came to the conclusion that cancer cells had no characteristics distinctive enough to allow them to be marked off from others; indeed, they were no more in most instances than ordinary embryonic cells. His theory of cancer was that, if the cells formed from the granules appearing in the original blastema did not follow out their respective life histories, so as to produce natural tissue, but continued merely to increase in number without developing, they formed a mass or tumor, and to this the name of cancer was given. They corresponded in form to the cells of malignant growths, and therefore the latter were nothing more than masses of embryonic cells. It was a purposeless growth, and therefore might, in contradistinction to benignant, correctly be styled malignant. The cells were usually contained in a newly-formed matrix with a good supply of blood-vessels. If the new material showed any attempt to grow, then the cell might become elongated until a simple fiber was formed. In this way he made a scale beginning with the cancer or simple cell growth, and so passing on with its development until he reached the simplest and most innocent pure fibrous tumor. In a later paper the author called attention to the fact that these cell masses differed according to the part of the body in which they grew; thus, cancer on a bone might contain osseous matter, cartilage, or a myeloid material; if from the choroid of the eye, would be melanotic, etc. Moreover, all these local characters might be propagated to other parts. These facts have always made the author feel skeptical as to the etiological value of any definite specific germ.

The Opsonic Theory and Its Practical Application to Medicine and Surgery.—G. Ross gives a clear and succinct account of the development of the theory of Wright and Douglas, regarding the nature of "opsonin," the substance essential according to this theory for phagocytosis, and acting not on the leucocytes, but combining with the microorganisms and preparing them for the leucocytes. The technical description of the clinical methods concerned cannot be reproduced here. The convenient mode of expression is to speak of the "opsonic index" in a given patient. The rules for the computation of the index are given in the original paper; *e. g.* when we say that a patient has an opsonic index of 0.5 to staphylococcus, we mean that his blood plasma contains but half the normal quantity of those opsonins which are essential to combating a staphylococcus infection successfully. The treatment of a bacterial infection consists in increasing the antibacterial substances of the blood by inoculating the patient with dead microorganisms of the same species, causing and maintaining the morbid process. The author gives his experience in certain cases of tuberculosis, both with a view to therapeutic results and to differential diagnosis. By this method he has been able to rule out tuberculosis in certain suspicious cases proving it to be, respectively, malignant disease of the lung, chronic bronchitis with emphysema, bronchiectasis, and general debility. The author, furthermore, expresses a most enthusiastic faith in the opsonic theory, and shares in the dictum of Wright that "we have, in the power of raising the antibacterial power of the blood with respect to any invading microbe, out of all comparison, the most valuable asset in medicine."

Opsonic Index of Tuberculous Patients Undergoing Sanatorium Treatment.—G. A. Crace-Calvert sums up

our present knowledge in this respect in the following propositions: (1) In slight, early cases the index appears to be above normal. (2) In acute cases it fluctuates greatly from day to day. (3) In chronic cases it appears to be below normal. (4) In sanatorium "cures," the index appears to be variable. "Undoubtedly," says Calvert, "a high index is of value if it can be maintained. A fluctuating index is not of much value. It must, however, be beneficial to the patient to have his diseased tissues bathed in a serum which is rich in opsonins, because if the bacilli are more easily taken up by the phagocytes, it gives him a better chance of combating his disease." In two instances Calvert has noted that after a few inoculations bacilli have not only diminished in numbers, but have also become "clumped," being broadcast before, and, as far as we know, the "clumping" shows that the bacilli are finding the conditions adverse to them. This point shows a possible relationship between the opsonins and agglutinins. It is proven that the new Koch tuberculin TR raises the opsonic index. There may be initial lessening of the resistance power. This is called the "negative" phase, but it is succeeded soon by its opposite. By careful spacing of the injections one positive phase can be made to follow another, with only a very short negative phase between. A second inoculation must never be given before the negative phase of the preceding one has passed off, for negative phases may accumulate, so to speak, and lead to a prolonged condition of low opsonic power. Hence our requisites are a frequent determination of the index and appropriate dosage of the TR. The greatest benefit from inoculation is to be obtained in those chronic cases of phthisis which with a fair amount of disease and a fair amount of cirrhosis and healing, are nevertheless practically stationary, whether they have tried climatic or sanatorium treatment. As we have seen, the index in such cases is usually below normal, and if we raise it by inoculation we probably give the patient another impetus, which, by maintaining his serum in a good resisting condition, may enable him better to combat the disease and lead less the life of an invalid. ,

The Electromotive Changes in Heart-Block.—The patient of G. A. Gibson, on whom observations were made, was a man of fifty-six years, with bradycardia. Examination with the fluoroscope showed that the auricles contracted three or four times for each ventricular systole. The electric variations were studied by means of a capillary electrometer. Leading off from the basal region of the precordia to the acid, and from the apical to the mercury, the usual diphasic movements of the capillary column were clearly seen preceding the apex beat, and evidently resulting from ventricular systole. But in the interval between these movements other smaller waves were distinctly seen, and can only be attributed to the systole of the auricles. As these latter movements were small, as observed by the direct method with the microscope, it was impossible to be certain of their exact character, but they seemed, like the ventricular, to be diphasic. When thrown upon the screen by means of the projection microscope, they were obviously diphasic in their character.

Berliner klinische Wochenschrift, July 2, 1906.

The Treatment of Pulmonary Tuberculosis by Hyperemia.—Leo discusses this subject and reaches the conclusion that the attempt to treat pulmonary tuberculosis by the artificial production of hyperemia of the lung is a rational measure. Of the various means that can be employed to produce this hyperemia, those causing passive congestion are the only form that can be considered. This can most simply be secured by placing the patient in the recumbent position, with the thorax low down, the head slightly elevated, and the legs very much so. Even at night the upper portion of the body should be depressed and not elevated, and the daily duration of this posture should be gradually increased. A tendency to hemorrhage is an absolute contraindication to the method. The author has employed this plan in thirty cases, and considers that on the whole the results are encouraging, though certain disadvantages were noted in a few instances. The author states that further observation must show whether the suction apparatus of Bier can be applied for this purpose or not, and he also proposes to try the effect of tuberculin as an adjuvant to the treatment.

Experimental Observations on Blood Pressure in Nephritis.—Brodzki discusses the various opinions current in regard to this subject, and reports the results of experiments on rabbits made to consider especially the following two points: (1) Whether nephritis of itself causes a rise in blood pressure, and (2) whether certain additions to the dietary produce a rise in pressure, or augment this if already present. The substances used for evoking the experimental nephritis were cantharidin and uranium. The kidney lesion produced by the former agent is principally a glomerulonephritis, and is not accompanied by any elevation of blood pressure, but uranium nephritis does cause a rise in tension. Neither water, sodium chloride, milk, nor meat extract have any effect on the arterial blood pressure worth mentioning, when nephritis already exists. The author therefore concludes that in acute nephritis elevations in blood pressure are not produced to the degree usually alleged as the result of clinical tonometrical determinations, and he infers that in view of the importance of accuracy in this matter it is necessary to investigate the problems involved more closely.

Münchener medizinische Wochenschrift, July 3, 1906.

A New Method for Quantitative Sugar Determinations.—Bendix and Schittenhelm have devised a piece of apparatus which is intended to simplify the quantitative determination of sugar in the urine. Equal parts of the urine and of 10 per cent. sodium or potassium hydrate solution are boiled together for one to two minutes, and the mixture is allowed to cool. A graduated tube is filled with the mixture to a certain point, and the color of the fluid is compared with that of a standard contained in a sealed glass tube. By diluting the urine mixture with water until the color corresponds to that of the standard, the percentage of sugar can be read off directly from the graduations on the tube. The ordinary urinary pigments do not interfere with the determination, though the urine must be free from adventitious coloring matter coming from ingested drugs, particularly phenol preparations. The method is not available for any sugars other than glucose, and one of the usual qualitative tests should always be employed first. Comparative observations showed that the error of the method is within 0.5 per cent., and that it is more reliable than the fermentation determinations. The presence of albumin does not interfere with the method.

The Treatment of Esophageal Stenosis.—Gerhardt values very highly the use of morphine to relieve dysphagia in cases of esophageal stenosis, and describes several instances in which great relief was afforded in this way. While the treatment is, of course, purely symptomatic, when the stricture is due to a malignant growth it enables the patients to take liquid food by mouth for long periods after deglutition has become impossible under other conditions. The drug is best given about fifteen minutes before meals, and does not appear to have any undesirable effect on the general conditions. Its efficacy is ascribed to the relief of muscular spasm.

The Diagnostic Value of Spirochetes in Congenital Syphilis.—Simmonds, as the result of the examination of a large number of cadavers of stillborn children and of infants that died shortly after birth, comes to the conclusion that the demonstration of the *Spirochæta pallida* in the organs in such cases is sufficient to justify the diagnosis of syphilis. A negative result in macerated fetuses appears to exclude the likelihood of syphilis, but in dealing with the bodies of children that have lived, the absence of the organisms must be interpreted more cautiously. The spirochetes were found in a great many of the tissues, including the meconium, but were most numerous in the liver and the wall of the intestine.

French and Italian Journals.

Symptoms of Basedow's Disease Without Goiter or Exophthalmos.—Libotte has recently reported a case of Basedow's disease in a woman thirty years old. He still has the patient under observation. On the least movement she suffered from palpitation of the heart which made walking impossible. Perspiration was habitual; tremor in the hands and arms made sewing and writing impossible. The stools were softer and more abundant than normal. The skin was always hot. Nevertheless there was no other sign of Basedow's disease, either in the neck or in the eyes. Physical examination did not show any signs of cardiovascular affection. Under the influence of the application of the galvanic current these troubles disappeared. The case is interesting from the absence of goiter and exophthalmos, and from the fact that the diagnosis was confirmed by the positive and rapid results obtained from galvanotherapy.—*Le Bulletin Médical,* June 2, 1906.

Action of Roentgen Rays in Malarial Infection.—Alberto Demarchi experimented on the effect of the *x*-ray on the malarial organism and on the tumor of the spleen in several cases of chronic malarial poisoning, with marked enlargement of the spleen. Examination of the blood was made to ascertain the effect of the treatment on the parasites. The author concludes that the rays applied over the spleen have no effect on the course of the infection, nor on the number, vitality, and development of the parasites, neither does it affect the occurrence of relapses. It does, however, produce a reduction in the size of the splenic tumor, but only after medication has put an end to the febrile attacks.—*Il Policlinico,* June, 1906.

Book Reviews.

THE OPERATIVE TREATMENT OF FRACTURES. By W. ARBUTHNOT LANE, M.S., F.R.C.S., Surgeon to Guy's Hospital, and Senior Surgeon to the Hospital for Sick Children, Great Ormond Street. London: The Medical Publishing Company, Limited, 1905.

ARBUTHNOT LANE operates in all cases of simple fractures of the long bones in which he is unable to obtain accurate apposition of fragments when the restoration of the bone to its normal form is of mechanical importance to the individual. In the present brief monograph he gives an account of his operative work in wiring and fastening the fragments of broken bones, and illustrates his results by radiographs. He believes that the teachings of the textbooks as to the possibility of restoring the form of broken bones and the satisfactory results of their treatment are absolutely false, and that the *x*-rays show that it is impossible to put displaced fragments of broken bones in accurate apposition without an operation. The mechanics of fractures, the special features of the several fractures of the long bones, and the operative technique employed by the author are dealt with in considerable detail.

The book is quite in contrast with that of Guermonprez (Études sur le Traitement des Fractures des Membres, Paris, 1906), recently published, in which sixteen hundred pages are devoted to the advocacy of massage and mechanotherapy in the treatment of fractures of the extremities, and the simultaneous appearance of the two books shows once more the divergence of opinions which still exists among surgeons as to the best ways of handling fractures.

NOTES ON GENERAL PRACTICE. By S. M. HEBBLETHWAITE, M.D., Lond., etc. London: The Scientific Press, Limited, 1905.

THIS pocket volume aims to put together a series of practical hints on subjects of vital interest to general practitioners. The notes are not arranged systematically, but ramble from "Peritoneal Catastrophies" to "Rheumatism, Pneumonia, Diphtheria," etc. Special sections are, however, devoted to surgical notes; notes on infants and children, and obstetrical notes. The author has drawn his material both from his own experience and from standard medical works, and the notes are of so practical a character that a busy physician will find use for them almost daily. They are written in an easy, conversational style and make pleasant reading during the odd moments, of which we are supposed to have so many.

SUL TRATTAMENTO CHIRURGICO DELLE NEFRITI MEDICHE. Dott. GIUSEPPE QUATTRO-CIOCCHI, Prof. l. d. di Patol. Spec. Chirurgica nella R. Università di Roma. Milano-Roma: Società Editrice Dante Alighieri di Albrighi, Segati e C., 1906.

THIS monograph on the surgical treatment of "medical" nephritis presents a very complete and all-sided discussion of this still unsettled problem. In many respects the present volume is modeled after the Portuguese monograph of Francisco Gentil: "Tratamento Cirurgico do Mal de Bright," which we had the pleasure of reviewing in this column some months since. Quattro-Ciocchi's work, however, lacks the strikingly beautiful illustrations of Gentil's book, and is more condensed and a year nearer to date. In both books the history of the movement towards surgical treatment in Bright's disease is recorded, the arguments of the various leaders of this movement—Harrison, Israel, Edebohls—are set forth, the experimental proofs now extant in favor of and against these arguments are detailed, and the clinical data thus far published are analyzed. Guiteras's table of 120 cases, the most complete thus far published, is given in full in the Italian book. The practical conclusion drawn by Quattro-Ciocchi is just as favorable to Edebohls's operation as the view taken by Gentil, for the former, whose book is now under review, declares essentially in agreement with the postulates of Edebohls, and regards the operation of decapsulation as a most important accessory to medical treatment, to be employed especially when medical measures fail.

DISEASES OF THE NERVOUS SYSTEM RESULTING FROM ACCIDENT AND INJURY. By PEARCE BAILEY, A.M., M.D., Clinical Lecturer in Neurology, Columbia University, etc. New York: D. Appleton & Co., 1906.

THE now well-known book, "Accident and Injury in their Relations to the Nervous System," which Dr. Bailey wrote in 1898, dealt chiefly with those functional derangements of the nervous system resulting from injuries, which are known as traumatic neuroses. In this book the differentiation of these neuroses from organic nervous affections due to accidents was necessarily given, but the organic conditions were not gone into further than needful. In the present volume, which must be regarded as an expanded and broadened treatise upon the subject of nervous diseases due to injuries, both functional and organic disorders due to accidents are considered from the viewpoint of the neurologist and the medicolegal expert. The usefulness of the volume is thus at least doubled in its present form, and physicians called upon to treat and to testify in cases of accidental injuries simply cannot do without Dr. Bailey's book.

In its present form the treatise shows the same excellent features that characterized the earlier book, but is distinguished by a greater systematization, a deeper and broader elaboration of the text, and a clearer view of the relations of injuries to the nervous system as a whole. The general considerations embrace the methods of diagnosis; part I. deals with organic affections, while part II. concerns the functional effects of injuries. Part III. embraces the medicolegal aspects of nervous disorders, following injuries, the methods of detecting simulation, the duties of the medical expert, etc. A necessarily brief but clear and practical chapter on the treatment of functional traumatic neuroses will find favor with the general practitioner. The chapters on the treatment of organic lesions are written with the outlook of the neurologist rather than of the surgeon, though surgical procedures where needed are briefly set forth.

Dr. Bailey's new book will prove of great help in many a puzzling case, especially to physicians far from centers where experts such as the author can be consulted.

THE PRACTICE OF GYNECOLOGY. In Original Contributions by American Authors. Edited by J. WESLEY BOVÉE, M.D., Professor of Gynecology, George Washington University. Washington, D. C. Philadelphia and New York: Lea Brothers & Co., 1906.

THIS is a new treatise on gynecology, one occupying a position midway between the "system," in several volumes and by many authors, and the individual treatise. The contributors to this volume are seven in number, to wit: Drs. J. Riddle Goffe, G. Brown Miller, George H. Noble, Benjamin R. Schenck, Thomas J. Watkins, and X. O. Werder, and the editor. The latter has written several chapters on diseases of the urinary tract, anus, and rectum in woman. The introduction of these subjects in a treatise on gynecology is novel, yet, on consideration, eminently logical, since all the pelvic organs in woman are so intimately related that disease of one is easily transmitted to another, or at least gives symptoms which are confusing. The volume is one of a series which includes similar composite treatises on obstetrics and on pediatrics. The illustrations are numerous and good, many of them, however, not original. The work is adapted to the needs not only of the gynecologist but also, and especially, of the general practitioner, and to the one as to the other it can be warmly commended.

A TEXT-BOOK OF MATERIA MEDICA, THERAPEUTICS, AND PHARMACOLOGY. By GEORGE F. BUTLER, Ph.G., M.D., Associate Professor of Therapeutics in the College of Physicians and Surgeons, Chicago. Fifth Edition, thoroughly revised by SMITH ELY JELLIFFE, M.D., Ph.D., Professor of Pharmacognosy and Instructor in Materia Medica and Therapeutics in Columbia University (College of Physicians and Surgeons), New York. Philadelphia and London: W. B. Saunders Company, 1906.

IN this edition, which has been adapted to the eighth revision of the U. S. Pharmacopœia, many changes have been made which are decidedly in the nature of improvements. The book, although containing new matter, has been reduced in size by the elimination of old and obsolete matter, and by the use of a more compact type. A new classification has been made, the drugs being grouped so as to bring together those whose predominant action is on one organic system of the body. The results of the recent activity in the field of physical chemistry are also incorporated in the work and brought in coordination with the heretofore accepted facts of the science of therapeutics.

HEATH'S MANUAL OF MINOR SURGERY AND BANDAGING. Thirteenth Edition. Revised by BILTON POLLARD, F.R.C.S, London. Philadelphia: P. Blakiston's Son & Co., 1906.

THIS little book has evidently filled a want among English medical students, to judge by the number of editions which it has gone through, the last of which has been brought up to date as much as possible. It contains the usual accounts of minor operations, dressings, and bandaging, is written in a very simple manner, and will probably prove of value for the English hospital interne. Some of the illustrations, particularly of instruments, had better been omitted, for they are certainly not representative of the patterns used at the present day—the cautery illustrated on page 188 will hardly be found in a modern hospital. There is a very good chapter on anesthesia by Dr. Buxton.

Society Reports.

MEDICAL SOCIETY OF NEW JERSEY.

One Hundred and Fortieth Annual Meeting, Held at Atlantic City, June 19, 20, and 21, 1906.

(Special Report to the MEDICAL RECORD.)

DR. ALEXANDER MARCY, JR., FIRST VICE-PRESIDENT, IN THE CHAIR.

Tuesday, June 19—First Day.

THE morning's session was devoted to the reading of the minutes of the previous meeting and of the reports of the various committees. The afternoon's session was begun with a prayer by the Rev. J. Holbrook Townsend. This was followed by an address of welcome by Dr. Thomas K. Reed of Atlantic City.

The Tendency of the Organism to Limit Pulmonary Tuberculosis.—Dr. THEODORE SENSEMAN of Atlantic City read this paper. He said it was of the utmost importance that the equilibrium of metabolism be maintained. The symptoms of the disease showed metabolic change; the toxins were to be met and neutralized; the cells of the body should receive proper and sufficient nourishment in order that they might ably cope with the toxins and neutralize them. The rationale of the treatment was the conversion of catabolism into anabolism. The question of diet was considered. Rest should be insisted upon if the temperature was 103° or over. One should study the individual and see that he got pure and fresh air, whether dry or moist did not matter, so long as it was fresh and the patient did not breathe it over.

Two Cases of Edema of the Larynx.—Dr. F. C. ARD of Plainfield, N. J., made this report. The first patient had an attack of tonsillitis and some two weeks later was admitted to the hospital for difficulty in breathing. Examination showed normal pharynx, edema of the ventricular bands, arytenoids, and posterior wall of the larynx, brawny swelling of the neck extending almost to the clavicle, marked dysphagia, dyspnea, and hoarseness; the patient was very restless. The temperature was 100.2°, respiration 30, pulse 112. On the following day the symptoms improved, and the urine examination showed albumin, granular, hyaline, and blood casts. There was continued improvement with lessening of the swelling in the neck for four days when the patient's condition rapidly became worse, with temperature 103.4°, pulse 136, patient in a comatose state, marked twitching of the arms and legs, almost total suppression of the urine, pulse full and bounding. The median basilic vein was opened and twenty ounces of blood extracted. The same amount of saline solution was injected. Tracheotomy was performed, a large tube inserted, at the same time, an abscess of the neck was opened, from which a considerable quantity of pus escaped. The following day the patient was rational, his general symptoms improved, and he made a rapid recovery. The second patient complained of earache. An examination revealed the ear to be normal, but a tender and swollen spot was found underneath the tongue. The swelling underneath the tongue rapidly increased. The patient's home was in New York, and she was making a short visit in Plainfield. She stated that if her illness was serious she wished to return immediately to New York. She was advised that it might become serious and she accordingly returned. Subsequent history was furnished by Dr. F. W. Murray, surgeon of the New York Hospital, who was called in by the family physician to open the abscess underneath the tongue. Ether was administered, edema of the glottis supervened, and a hasty tracheotomy was done. Owing to a heart lesion further operative interference was stopped. On the following day the abscess ruptured in the pharynx. The patient recovered. In further remarks, Semon's conclusions were assumed to be correct, that the various forms of acute septic inflammation of the throat and neck, heretofore considered as so many different diseases, were, in reality, pathologically identical; they merely represented degrees, varying in virulence, of one and the same process. Some of these cases were mild, in others the toxic element was so overwhelming that death almost invariably resulted. Prodromal symptoms were sometimes present, such as headache, sore throat, fever, and general malaise.

Dr. NORTON LUTHER WILSON of Elizabeth said that any inflammatory condition surrounding the larynx was capable of producing edema of the larynx. Iodide of potassium had been known to produce it after the administration of three drams of a 5 per cent. solution. Influenza as well as malaria might cause it, and Dr. Wilson had seen it develop in cases of angioneurotic edema. He made a plea for tracheotomy in cases of edema of the larynx, and reported an instance in which he temporized in the afternoon by simply puncturing the edema, the patient dying that night before help could reach him. He believed that if he had performed a tracheotomy the man would have lived.

Dr. TALBOT R. CHAMBERS of Jersey City said that in these cases of edema of the larynx he used nitrate of silver in 25 per cent. solution. He reported a case of lupus of the larynx which he operated upon; the patient lived five years, but died from a recurrence.

Dr. JOHN G. RYERSON of Boonton reported a case in which the old-fashioned gum lancet was jabbed down here and there, with recovery following. He did not believe the disease to be the same to-day as it was thirty or forty years ago.

The Prevention of Scarlatinal Nephritis.—Dr. FLOYD MCEWEN of Newark said that nephritis was a very serious sequel of scarlet fever, and every effort should be made to prevent its development. The internal use of bisulphate of sodium was of service. He also considered the importance and management of the diet.

Dr. DAVID E. ENGLISH of Milburn said that scarlatinal nephritis was due to the elimination of toxins by the kidneys and he condemned the old practice of greasing the skin, thus throwing greater labor upon the kidneys. It was his practice to apply to the skin soap suds and alcohol, and take from the skin all of the poison that he could.

Dr. FRANK WILCOX PINNEO of Newark said that if convulsions and albuminuria occurred early in the disease an acute exudative nephritis was present and would be followed by recovery; but if the convulsions occurred after the third week or later, without a preceding albuminuria, the prognosis was less favorable.

Examination of Eyes and Ears of School Children.—Dr. LINN EMERSON of Orange gave the results of Dr. Allport's plan of examination of the eyes and ears of public school children in the Oranges, and made a strong plea for its universal adoption.

Dr. EDWARD E. WORL of Newark said that the measure advocated by Dr. Emerson was a good one and should be extended to the entire State of New Jersey.

Dr. TALBOT R. CHAMBERS of Jersey City was heartily in favor of the scheme as proposed; this was in the line of progress and everything should be done to make the children healthier and better.

Dr. DAVIS of Camden said often irregular attendance at school was an indication that something was wrong with either vision or hearing.

Dr. N. L. WILSON of Elizabeth also discussed the paper.

The Value of Tartar Emetic in the Treatment of Traumatic Tetanus and Cerebrospinal Meningitis.—Dr. DAVID ST. JOHN of Hackensack took this as the subject of his annual address. He reported cases that had occurred in the Hackensack Hospital which were cured by giving tartar emetic in large doses, a treatment that had been given him by Dr. William R. Bross, Medical Director of the Equitable Life, and which Dr. Bross had used successfully while in the tropics.

The System of Medical School Inspection of the Department of Health of the City of New York.—Dr. Thomas Darlington, Commissioner of Health of New York City, considered the prevalence of unreported cases of acute infectious and contagious disease among the school children, the transmission of contagious diseases in the public schools, the control and elimination of these by inspection and exclusion from school, visiting homes of absentees, etc. Investigation by the Board of Health concerning public schools and the transmission of disease was begun October 18, 1896; in March, 1897, a system of medical school inspection was begun. In June, 1902, sixteen oculists were appointed with particular reference to trachoma. A revised procedure was adopted, a card index, listing the names of children with history of their diseases, and the appointment of school nurses, followed. In December, 1902, a regular corps of nurses was appointed. In December, 1902, there was established an eye hospital and dispensary under the control of the Board of Health and, in 1904, a second eye hospital and dispensary was opened. In March, 1905, there was established a complete physical examination of school children.

Dr. Walter B. Johnson of Paterson said that what had been done by Dr. Darlington was of great importance, but that the physicians now should get together and try to curb the educators. It made no difference how hygienic the schoolhouses were, or what was the condition of health of the child, if the educator was to be allowed to pile an enormous amount of work upon the students by advancing the standards to a point the average child could hardly attain. This advancement of education beyond the point of tolerance was as unwise as to erect badly constructed schoolhouses.

Dr. Edward E. Worl of Newark agreed with Dr. Johnson and thought it would be a wise plan to return to the old system of three hours a day. In Newark a very large number of school children had enlarged glands and many cases of measles formed the foundation for the development of tuberculosis in after life.

Dr. Frank D. Gray of Jersey City told of the hopeful outlook that now existed because of the very efficient plan of reaching the public through the newspapers and various magazines, and in popular lectures in schools, colleges, and public halls.

Dr. Richard P. Francine of Montclair said that the public in the State of New Jersey was not, as a rule, educated to appreciate the value of medical school inspection, and it should be the aim of the Society to educate the public up to this.

Oration in Surgery.—Dr. Thomas W. Harvey of Orange introduced his paper with a few considerations of the preantiseptic period and a reference to the rapid development of surgery, the supplanting of medical treatment by surgery in diseased conditions situated below the abdomen, and the fact that so many more medical men were doing surgery than formerly. The tendency of the schools to train students as general surgeons rather than as general practitioners was commented upon. With all the increase of surgical work and of the number of surgeons, there was, however, a steady progress toward conservatism in surgery, the essentials of which were claimed to be early operation, wide incision in malignant disease, preservation of organs in suppurative and benign disease, and protection of the patient during the operation. The rest of the paper was devoted to the consideration of the clinical laboratory as an adjuvant to surgery, and illustrations were given of the many ways in which surgical diagnosis and prognosis were facilitated by its assistance. The use of cryoscopy in determining the adequacy of the renal function, when considering the question of removing a diseased kidney, the relation of the excretion of indican and glycerin in the differential diagnosis of diseases of the digestive tract, the value of the differential blood count in measuring the severity of inflammatory processes, and the application of the studies of Crile and Cushing in blood pressure to the uses of surgery, were all considered. He concluded his address with a brief mention of the possibilities of further surgical progress, and the statement that many things had to be learned and many things forgotten before we could say with Ambroise Paré: I have so certainly touched the mark at which I aimed, that antiquity may seem to have nothing where it may excel us, besides the glory of invention; nor posterity anything left but a certain small hope to add some things, since it is easy to add to former inventions."

Oration in Medicine.—Dr. Joseph Tomlinson of Bridgeton then delivered this oration, taking as his subject the study of structure and function in relation to practical medicine. The relative importance of anatomy and physiology in comparison with the other branches of the science of medicine was a factor variously estimated. These subjects were regarded by the average undergraduate in medicine very much as were Latin and Greek by most students in the classical course in our colleges, as dry and devoid of interest, and worthy only of being forgotten as soon as examinations had been passed. Specialists and a very small minority of general practitioners realized that a knowledge of structure and function was an absolute requisite to definite diagnosis and rational treatment. A plea was made for a better and more general understanding of these subjects by the general practitioner, as he believed it was the very essence of scientific work. As the knowledge of normal structure was supplemented by a knowledge of structure in disease, and as macroscopic investigations were amplified by microscopic discoveries, they came to be looked upon as a means of discovering the nature and cause of disease quite as much as preliminary studies. There was, perhaps, no better exponent of the men who helped to stamp them as means to this end than the late Professor Virchow. Most of his eventful life was spent in propagating his theory of the anatomical principle in disease. The study of comparative anatomy also bore an important relation to medical science, involving, as it did, the theory of evolution and the variation of species. It was of especial interest to the physician, because of its bearing upon the question of heredity. Anatomy and physiology were, therefore, not only descriptive of normal structure and normal function, but were also requisite for the detection of disease, the comprehension of its nature, and the interpretation of its symptoms. The attitude of the physician toward these subjects would determine his standing as a scientific man. How could the ordinary physician be brought to a higher standard of knowledge in these branches? The suggestions here made were, as far as they went, the outgrowth of practical experiences of many years with the specialist on the one hand and the general practitioner on the other. They might be formulated as follows:

1. The general practice of medicine should stand for something definite, with specific requirements and limitations. In the final analysis the qualities demanded in the physician were twofold, consisting of ideals and ideas. Ideals alone would not make a competent physician. He must also possess adequate knowledge, judgment, and studiousness. Diagnostic ability comprehended the latter requisites. Failure in diagnosis on the part of the general practitioner might be due to faulty methods of examination, quite as much as to lack of knowledge of structure and function. Diagnostic duty was not completely performed by a naming of the disease. Every disease must be studied with reference to the individual. Age, sex, habit, as of plethora or the reverse, individual idiosyncrasy, drug susceptibility, temperament, coexisting disease, hereditary influences, all had a bearing upon the proper estimate of a case. The prevailing carelessness in this phase of diagnosis was evinced by the widespread habit of prescribing ready-made tablets of complex formulæ, without regard to the individualities of the case.

2. The physician should constantly endeavor to refresh his memory in anatomy, physiology, and pathology, and

should seize every opportunity to add to his knowledge on these subjects. Autopsies should be more frequently sought, and subjects chosen from this field should be more frequently discussed in the county societies. The possibilities of awakening a scientific spirit were the most desirable of all the results to be hoped for in the complete organization of the medical profession. There was no better opportunity for the physician to study pathology than by witnessing surgical operations. Nothing had done so much to convince the physician of the futility of medical treatment for appendicitis as actual demonstrations on the operating table. And nothing could so impress him with the seriousness of a chronic middle-ear discharge, as a mastoid operation or an operation for infective sinus-thrombosis.

3. Some changes in the methods of medical teaching were evidently required. Either intentionally or otherwise there had been a growing tendency to specialism in medical teaching. Now the plea was going up from various quarters of the profession to give us the physician first and make the specialist afterward. It was to the teacher we must look for a readjustment of methods in medical education. His appreciation of his duty, his conscientious desire to perform his duty, and his willingness to let the profession of teaching be the end rather than a means to further private ends, would form a safe basis for the solution of this problem. Such were some of the methods which had suggested themselves for raising the standard of work in the rank and file of the medical profession. As the broad and comprehensive grasp of great truths intelligently expressed by the methods of his art constituted the artist, so the work of an intelligent physician involved the personal application of broad principles. Without the ability to do this he went through the form of his work without getting at the substance of it, and his efforts bore the same relation to what they should be as a doggerel rhyme bore to a poem of Tennyson. And as the artist, whether his field was in painting, in poetry, in sculpture, or in the drama, should ever strive to impress the lofty ideals of beauty, truth, and virtue, so it became the duty of the physician unceasingly to strive toward a better knowledge of the structure and functions of the wonderful piece of mechanism which was committed to him, as a practitioner of the healing art, in sacred trust.

Fibroid Tumors of the Uterus.—Dr. George H. Balleray of Paterson read this paper. The points that he wished to draw attention to were as follows: That but little was known of the etiology of fibroids; that they almost never appeared before puberty, and rarely developed after the menopause; that they were more common in women of the negro race than in white women; that heredity was a factor in their causation; that the mere presence of a uterine fibroid was not in itself an indication for operation; that palliative treatment often sufficed to carry the patient beyond the menopause, and that after that period the tumor often disappeared spontaneously; that in pedunculated growths and tumors that could be enucleated without too much injury to the structures of the uterus, myomectomy should be the operation of choice; that when hysterectomy was necessary, supravaginal amputation was a much better operation than panhysterectomy or the combined method; that when pregnancy complicated a fibroid tumor of the uterus the patient should be allowed to go to full term, and when labor set in the case should be treated according to the indications present at that time.

Dr. Edward J. Ill of Newark said that in the records of the Johns Hopkins Hospital there were recorded 1,310 cases of uterine fibroids, and only one that appeared to have gone on to malignancy. He said he had never seen a case of malignancy occurring in a uterine fibroid. These patients should be watched very carefully; while the fibroids increased in size before menstruation, they decreased again afterward; he treated them with cotton-root extract in 30-drop doses before and during the menstrual period, and this appeared to have a marked influence. With regard to pregnancy and fibroids, of twenty cesarean sections, only one was performed because the fibroid obstructed the passage of the child. He had many times expected to be called upon to do a cesarean section, but there followed a retraction of the lower uterine segment and an ordinary labor.

Dr. Balleray was glad that Dr. Ill emphasized the fact that there were so few cases in which a true malignancy appeared in the uterine fibroid. With regard to pregnancy complicating fibroids, he said he had written a paper some time ago in which he reported a number of such cases. In several delivery was made quite difficult. In every case, however, within eighteen months from the time of delivery the tumors, which were sometimes as large as a uterus at the sixth month, had entirely disappeared. He advised letting nature alone and not interfering unless with positive indications.

Wednesday, June 20—Second Day.

Metastatic Panophthalmitis.—Dr. Charles J. Kipp reported two cases of metastatic panophthalmitis. The first patient had been operated upon for appendicitis. For a week after the operation there were no signs of sepsis, then occurred phlegmasia alba dolens of one leg. After recovery from this there followed a very painful inflammation of the knee joint, a profuse diarrhea, then metastatic inflammation of the right eye, followed on the next day by inflammation of the other eye. There was total blindness. Death occurred sixty-one days after the operation. No autopsy was allowed. In the second case reported there was an extensive laceration of the foot and leg, complicated by septicopyemia and endocarditis, with metastatic ophthalmia of the left eye, followed in a day or two by the same disease of the other eye. Death followed, and at autopsy, with the exception of an infarct in the kidney, there were no metastases found in any part of the body except in the eyes. A report of the microscopical findings was given. There was flocculent exfoliation in both chambers of the eyes. The retina was in folds, caused by contraction of the sclera. The corneal epithelium was in good condition and Bowman's capsule was well marked. The membrane of Descemet was present, but indistinct. The iris was swollen and infiltrated. There was a purulent exudate surrounding the ciliary processes. The choroid was not thickened to any extent, but was filled with small round cells.

Dr. Walter B. Johnson of Paterson said he had seen only two cases, one following a puerperal pyemia, the other an endocarditis. The books stated that cerebrospinal meningitis, typhus fever, thrombus of the orbital veins, endocarditis, and pleuropneumonia were responsible for this form of infection, but they said little or nothing about its following injury or operation. There seemed to be a difference of opinion as to whether the panophthalmitis started in the retinal or in the choroidal vessels, or whether the infection was through a small embolus or a thrombus of the choroidal vessels.

Dr. Sutphen of Newark had seen one very appalling case, occurring in a man, following an attack of cerebrospinal meningitis.

Dr. Norton Luther Wilson of Elizabeth said he had never seen a case of panophthalmitis following a surgical operation, but he had seen three cases, one following endocarditis, one mumps, and the other pneumonia.

Pathological Report.—Dr. Philander A. Harris of Paterson presented the pathological report of eight cases of unruptured tubal pregnancy, proving his contention that they were true cases. (See Medical Record, July 8, 1905, page 75.)

Nutrition During the First Two Years of Life.—Dr. Henry L. Coit of Newark opened this symposium by considering the universal failure of maternal feeding and how best to conserve breast feeding. After speaking of the principles of infant feeding, he took up the methods of substitute feeding—empirical, commercial, mechanical,

mathematical, natural, and rational. There should be a flexible baby, a flexible mixture, but an inflexible principle.

Digestion of Fats, Proteids, and Carbohydrates in the First Year.—Dr. J. Finley Bell of Englewood offered the following conclusions: (1) The discovery of the gastric steapsin was most important, since it explained why infants could take and thrive on a high percentage of fat long before the pancreatic steapsin was fully developed. (2) The infantile digestive apparatus was fully equipped at birth for the digestion of the proteids necessary for its growth and development. Trypsin was the first enzyme of the pancreatic juice to develop. (3) The fat must be fluid and soluble, *i.e.* of a low melting point, in order that it might be digested. (4) The milk of many cows, particularly the Jersey and Guernsey, contained a highly insoluble fat, and should not be employed in infantile dietetics. (5) Goat's milk, with its soluble fats, fitted it for infantile feeding. (6) The employment of undextrinized cereal gruels during the early months of life was never useful, and frequently injurious. (7) Dextrinized gruels possessed no advantage over sugar solutions, and hence were unnecessary. (8) Whey cream mixtures of either cow's or goat's milk, preferably the latter, because of its soluble fat, prevented the formation of large curds by diminishing the amount of casein, substituting therefor a like amount of digested whey proteid albumin. (9) Infants would frequently digest and thrive on simple dilution of goat's milk. (10) During the latter months of the first year the child should have cereals, preferably in the form of jelly and fed with a spoon. These should include oats, wheat, and rice.

Suitable Diet During the Second Year.—Dr. Margaret P. Brewster of Grantwood read this paper. She advised a more liberal feeding after the ninth month, and recommended the use of diet lists for use during the second year. She also gave some suggestions for overcoming constipation after the nursing period, giving personal experiences along this line.

Second Year Disorders of Infantile Digestion.—Dr. Alex McAlister of Camden read this paper. He said that second year digestive disorders of infants were not less severe, but were less frequent than those of the first year. Some cases were carried over, as of puny or sickly infants; other cases were acquired incidental to normal growth, weaning, etc. The latter cases belonged to the scorbutic, the rachitic, the overfed, and the wrongly-fed. A child's propensity to eat everything and to swallow what could be put into the mouth must figure in proper diagnosis and treatment. In the search for cause emetics and cathartics were essential. Mothers needed education that they might determine by other means than a child's greed the quantity of food proper to allow. In all acute disturbances only water or thin gruel, or both, and little or no milk, while the alimentary canal was being treated, should be allowed. This accomplished, one should return to the first year diet, allowing in addition only scraped meat and fruit juice in small quantities. In chronic disturbance, from whatever cause, one should go back to the first year food. Every return to second year food must be gradual.

The Etiology of Rachitis, Scorbutus, and Cretinism.—Dr. August Adrian Strasser of Arlington read this paper. He said these were the three great nutritional disorders of infancy, and he briefly reviewed the theories of their causation, all summed up as errors in nutrition.

Diarrhea in Infancy and Early Life.—Dr. Irvin H. Hance of Lakewood said that the fundamental principle in the consideration of these cases was individualization. He advised against feeding by rules laid down for the age of the child. One should not give the child too much attention, but keep it quiet. A flannel binder should be kept on until the baby was four months old. The alimentary canal should be cleaned out thoroughly, and the stomach and bowels should have a rest for twenty-four or thirty-six hours; then one might gradually work back to the ordinary diet. The four drugs in his armamentarium in the treatment of diarrheas occurring in infancy and early life, were calomel in small doses, castor oil in full doses, bismuth, and paregoric.

Dr. Henry L. Coit of Newark said that the indications for treatment were four in number, viz., elimination, support, rest, and feeding. In elimination the drug of greatest value was calomel, and it was better used as Fothergill of London used it, in large doses followed by a saline. Support was accomplished by the use of water, especially the feeding by a medicine-dropper of water as hot as could be borne. This was readily absorbed, and acted as both food and drink. Rest was obtained by the administration of opium. The feeding should be by the use of sterilized carbohydrates and albumins, but especially sterilized water.

Dr. David E. English of Milburn did not believe in regular feeding. He did not believe that the infant's organs could always digest the same amount of food and the same kind of food, in the same number of minutes. The old-fashioned method was about right: when the baby cried, feed it. The baby's organs of digestion could not be fully developed unless properly exercised. The child should be placed upon a moderately firm surface, without any clothes on, and he said it was surprising to see how much exercise the baby would get and how much it would do to earn its living by such exercise.

Dr. Judson Daland of Philadelphia said that the closest scrutiny of the discharges should be made, not only of the feces, but also of the urine. If large quantities of indican were present in the urine, the evacuation treatment was indicated. There was a very important relationship between indican in the urine and chemical changes going on in the intestines. Colonic lavage removed from the colon materials which might be the source of supplying toxin substances, and therefore was of value in some cases.

Dr. Richard Cole Newton of Montclair said that women attempted too many things. The cow did not do anything except produce milk. It seemed to him that the time had come when the physical life of women should be changed so that they could nourish their own children. He advised that a lesson should be taken from the cow, who devoted her life to this one function. Women should be kept away from clubs and afternoon teas.

Dr. J. Finley Bell of Englewood gave podophyllin instead of calomel in these cases, and with good results. Many protracted cases of diarrhea were the result of nephritis; therefore the urine should be examined with great care in those intractable cases. The object of pediatricians was not to make a perfect food, but to get a better knowledge of the chemistry of milk that could be adapted to a particular child. He said that when babies were nursed irregularly, one not only ruined the child but also the mother's supply of milk.

Dr. William H. Walling of Atlantic City had used with great success arsenite of copper in the diarrhea of infants.

Some Dietetic Errors and Their Effects.—Dr. W. Blair Stewart of Atlantic City read this paper. The indiscriminate mixing of food produced more harm and gastric disturbance than the eating of plain food alone. The tendency was to a complex diet of many things at meals, rather than a small quantity of wholesome, well-balanced food, and to the bolting of that. A little more sensible advice on diet and less medicine was required, and physicians should study cook-books and advise patients how to prepare foods. Mixing acid fruits and cereals at the same meal was condemned as a most common error. Sugar on cereals should be avoided, and a little salt used instead. The oat cereals were the worst in fermentive troubles and caused more disturbance than wheat. Cereals should be cooked for several hours. The widely advertised forms of predigested foods were condemned as almost useless—a very few excepted. The whiter the bread and the finer the flour, the less true food value it contained. Hot bread and rolls were considered unwholesome. Sugar was probably the most abused food product and must be used discreetly. Coffee, tea, and alcoholic liquors and condiments

were considered in turn. Mixing of foods was condemned as productive of troubles that would not be produced by the simple food itself if taken alone. Eight to fifteen different foods and one to four different drinks were taken at an average course dinner. Was it any wonder that digestive disturbances resulted and the cause was never apparent to patient or physician? The beautiful results of a digestive ferment in a conglomerate mixture of foods in a test-tube might appeal to the theorist as an argument in favor of such excesses, but such changes did not take place in the stomach and would not prepare the food for proper assimilation. Our hardiest and healthiest people were those who ate any wholesome food placed before them and who had done so since childhood. Constant hunger was an indication of disease, if present in a well-fed person. A small, properly selected, well balanced, and carefully taken diet would be better assimilated and produce more nutritive effects than the meal of a glutton. The manual laborer or mental worker did his best work on a light meal. Persons past fifty should be very careful in their diet, and avoid the stimulant foods, so that arterial tension was not raised. The person whose stomach was his god and who believed in eating everything that tickled his palate, was a danger to himself, a dietetic nihilist, and must be cautioned in no uncertain terms. Dessert was declared useless at the close of a meal; it was that much too much and better avoided The idea that a fish diet supplied phosphorus and acted as a brain food was declared a fallacy. The author dwelt briefly upon the exploded theory of the sex of the child being influenced by the diet of the mother, and classed it as irrational. The paper closed with the remark that it was wrong to rush to see our patients or to see them in the office, write them their prescriptions, or give them some medicine, and hurry them through for the next one because we had no time to give them proper dietetic and hygienic instructions. We should be specific in directions on these subjects in every case, and see to it that the advice was thoroughly understood and, better still, put it in writing for them.

Dr. Philip Marvell of Atlantic City said that Dr. Stewart did not exaggerate when he referred to the habit of people sitting down at table and eating from fifteen to eighteen different kinds of food. The majority of people would be far better off if they abstained from desserts. It would be better, too, to lessen the number of meals taken a day, especially when people were past the age of sixty or seventy. Greater comfort was to be had from two meals a day than from three, if the person was actively engaged in work, either mental or physical.

Dr. W. E. Darnell of Atlantic City believed that overeating was as bad as over-drinking, and it was just as bad to be intemperate at the table as it was to go out on a spree. A more simple menu would produce less gastric and intestinal disturbances. One could not eat meat alone and expect to have a perfect digestion. There should be a proper balance in the dietary.

Dr. Richard Cole Newton of Montclair advised that they should consider the rules of life as laid down by Fletcher. It made not so much difference what one ate, so long as one ate properly. The food should be chewed until all taste had been extracted. If one ate properly, according to these rules, indigestion, Bright's disease, headaches, etc., would pass away, never to return.

Dr. Henry L. Coit of Newark condemned the American breakfast. Milk and fruits should not be taken at the same meal, neither should meats and fruits.

Dr. Judson Daland of Philadelphia said that the amount of food for the professional man should be about one-quarter to one-half that required for the laborer. He very much opposed the eating of meat and milk at the same meal. For brain workers a meal without meat would do better. Fruits should be taken one hour before the meal.

Dr. Alexander Marcy, Jr., of Riverton agreed that the average individual ate too much, and this was particularly true of the medical man. As long as the American plan of living was continued, just so long would the average person overeat. The continental breakfast was better than ours.

A Brief Study of the Clinical Evidence of Some Infections that Apparently Enter the System Through the Faucial Tonsils.—Dr. Philip Marvell of Atlantic City read this paper, in which he considered the supposed function of the faucial tonsils and the frequency of their involvement in bacterial disease. (See Medical Record, June 9, 1906, page 950.)

Dr. W. Blair Stewart of Atlantic City reported a case of erysipelas, in which there was strong evidence to prove that the disease germs gained entrance through the tonsils.

The Surgical Treatment of Gastroptosis.—Dr. Henry D. Beyea of Philadelphia read this paper, in which he considered the application of the surgical as compared with the medical and mechanical treatments of this affection. The *x*-ray was of added value in the study of gastroptosis. A further report of the results of his treatment, the surgical plication of the gastrohepatic omentum, was given, as well as the indications for the surgical treatment. The principle of the operation was that by placing three rows of interrupted sutures of silk from above downward, and from right to left, either the gastrohepatic or the gastrophrenic ligament were so attached to the gastrohepatic omentum, using a broad transverse fold, that plication was formed in the ligaments, thus shortening the supports and lifting the stomach to its normal position. In fourteen of the cases the patients had suffered from five to fifteen years with the characteristic and very severe symptoms of gastroptosis. All were very much emaciated. These fourteeen cases were observed during periods of from three months to eight years, and in every instance there was improvement in health following operation, which was most remarkable, and the relief of the symptoms was complete. There was no mortality. The operation of plication was indicated in every instance of gastroptosis in which the patients were not comfortable and unable to assume their occupations and soical duties after the thorough application of medical treatment.

Dr. Gorden K. Dickinson of Jersey City was surprised that such permanent results could be obtained from a plastic operation upon the gastrohepatic ligaments which contained such a small quantity of fibrous tissue. The results of Beyer's treatment showed that he had given the profession something of great value.

Dr. Noble of Philadelphia said there seemed to be a decided lack of knowledge regarding the general question of gastroptosis, enteroptosis, etc. Personally he thought medical men were very apt to exaggerate the frequency with which the internal viscera were prolapsed; in their discussions they assumed that if the kidney was prolapsed all other organs dropped. His own opinion was that the stomach dropped often when other viscera did not, and this was true of the uterus. Therefore, in many cases, if the gastroptosis was cured, one cured the only trouble the patient had.

Dr. Frank D. Gray of Jersey City asked if it would not be a time-saving method to use the continuous suture over a piece of rubber tubing. The only objection he could see was a possible interference with the circulation in the gastrocolic and hepatic omentum. He emphasized the fact that they were dealing with a gastroptosis and not a gastric dilatation.

Dr. George H. Balleray of Paterson thought this condition was due more to the patient's mode of life. It occurred among females and was, in the majority of cases, due to faulty methods of dressing, tight corsets, skirt bands, etc. There was an absorption of the intraabdominal fat and the benefit, in his opinion, of an operation was in keeping the patients in bed and allowing a reaccumulation of fat. One should not be in too great a hurry to suspend the stomach. It was necessary that the abdominal wall should have a sufficient amount of fat and of retentive

power; cure really followed rest in bed and improvement of the general condition.

Dr. Henry D. Beyea of Philadelphia acknowledged the fact that neurasthenia existed with a general ptosis. The restoration to health following these operations was remarkable. The use of the tube referred to by Dr. Gray was unnecessary and not practical. It was very necessary to go as high as possible, introducing all the sutures, before one tied them. As regards dilatation associated with gastroptosis, in three of his cases this was diagnosed, but was found not to be present at operation. It was usually secondary to the gastroptosis, and if the latter was relieved the dilatation symptoms would be as well.

The Omentum and Its Functions.—Dr. G. K. Dickinson of Jersey City read this paper. The numerous blood-vessels and lax tissues of the omentum allowed of storage of blood when the general arterial tension was high. By venous anastomosis through adhesions, local congestion might be relieved. Through its large surface freely exposed to surrounding parts in motion, it became a rapid absorber of fluids by the blood stream. By the lymph stream it was a free carrier of white blood corpuscles, encapsulating solid particles. Through its cohesive tendency, apertures in the abdomen into which the omentum had been forced by intraabdominal pressure became more or less completely closed. Through its readiness to lymph formation and local proliferation, it became attached to infected parts, which were walled off, subsequently to be absorbed by phagocytic action; the peritoneal cavity was thereby protected. The majority of the phagocytes extruded into the peritoneum for its protection came through the omentum, largely from the general circulation, but in part from the tissues therein existing; subsequently to be attached to the surface of this tissue, taken into the lymph stream, and subjected to the cytolytic influences existing there. Lack of development of the omentum, or loss through operation, rendered one less resistant to peritoneal invasion. Hemolymph glands of the splenic type existing in its base supplemented the spleen if the latter was removed or its functions interfered with.

Etiology of Appendicitis.—Dr. T. H. Mackenzie of Trenton gave a survey of the anatomical, physiological, and histological peculiarities of the appendix and their bearing on the predisposing causes of this disease. He gave both clinical and exciting causes. He said that among the factors that appeared to render the appendix less resistant to bacterial invasion and the other determining causes of appendicitis might be mentioned defective blood-supply arising from angulation, contortion, bands, and adhesions. Impaired circulation and nutrition were also produced by ineffectual peristaltic efforts on the part of the appendix to rid itself of offending foreign bodies, such as calculi or inspissated fecal matter. Another significant factor in rendering the appendix less resistant to bacterial invasion was atrophy or retrogression of that organ.

Diagnosis of Appendicitis.—Dr. Ellis W. Hedges of Plainfield presented this paper, which was read by Dr. Chandler. In it he emphasized the importance of diagnosis, and said that it was apt to be overlooked. The diagnosis was based on the presence of pain, tenderness, and fever. The pulse was generally a better index of the gravity of an attack than fever. The breathing was largely thoracic and quickened. There was rigidity of the right rectus. There was some value in the leucocyte count. He then took up the differential diagnosis from pneumonia, diaphragmatic pleurisy, hepatic colic, right floating kidney with twisted pedicle, intestinal obstruction, gastritis, acute enteritis in children, foreign bodies in the cecum, perforation of gastrointestinal ulcers, typhoid fever, intussusception, tuberculous peritonitis, pyelitis, and hip-joint disease.

Complications and Sequels of Appendicitis.—Dr. Paul M. Mecray of Camden read this paper and considered peritonitis, abscess, obstruction of the bowel, gangrene, sepsis, phlebitis, hemorrhage, and other complicating conditions; also he considered adhesions, hernia, fecal fistula, pain, and neurasthenia, as sequels.

The Treatment of Appendicitis.—Dr. Frank D. Gray of Jersey City read this paper. (See page 130.)

Dr. E. LaPlace of Philadelphia said there was no easy road to the diagnosis of appendicitis; there were no symptoms, or set of symptoms, upon which we could depend. Microorganisms did not behave in the same way any two hours during the course of the disease in two patients. The fever, rigidity, rapidity of the pulse, and other symptoms would be different in different cases.

Dr. George H. Balleray of Paterson, referring to the difficulty of diagnosis, said he had seen a child five years old with an acute perforative appendicitis and peritonitis, in whom a diagnosis had not been made, and he had seen two other cases in which the attending physicians had made a diagnosis of ptomain poisoning; in one case the abdomen was filled with pus.

Thursday, June 21—Third Day.

Hysteria and Neurasthenia in Women.—Dr. M. J. Synnott of Montclair read this paper. He said that functional nervous derangements were frequently met with in general practice and that they were so common in America because we went so much to excesses and the laws of hygiene were so often disobeyed. Hereditary influence, education, environment, and overwork were considered among the etiological factors. He divided them into two forms, primary and secondary. The symptoms were cerebral, spinal, vasomotor, gastrointestinal, respiratory, circulatory, vesical, articular, and mental. Attention should always be paid to prevention, to hygiene, diet, exercise, and special symptoms.

The Treatment of Chronic Nervous Conditions.—Dr. W. G. Schauffler of Lakewood read this paper. What it was desired to accomplish was the cure of the underlying causes and the amelioration of the symptoms. The methods of treatment he considered were medicinal, mental suggestion, physiological therapeutics, climate, etc.

Dr. William M. Leszynsky of New York said the general practitioner did not get the best results in the treatment of these cases because he could not get rid of the influences which surrounded these patients. One of the most difficult problems of the day in New York City was to know what to do with those poor people who could not afford to pay for proper treatment, and he hoped that some philanthropist would come to their aid in providing and endowing an institution for the care of these poor but deserving patients. In the treatment of hysteria and neurasthenia one should first be sure of the diagnosis. Many cases were brought to the neurologist with a mistaken diagnosis. Only this winter he had seen four cases of brain tumor that had been treated for a long period of time for hysteria and neurasthenia, the mistake being not due to ignorance but to carelessness. Dr. Leszynsky agreed that the worse place to send these patients was to the sanatorium, where patients were too often allowed to talk and compare their symptoms. The smaller the sanatorium the better would be the results. For his own part he could see no objection to treating these patients at home. The moral management of these patients was more important, as a rule, than the drug treatment. Occasionally he used cascara sagrada or some hypnotic. As to the use of electricity, massage, sunlight, etc., all agreed that they were more or less efficient. He advocated the use of the hot-air bath. He had not the great faith in electricity that Dr. Schauffler had.

Dr. William H. Walling of Atlantic City said that electricity should be used with some discrimination, and only trained assistants should administer it. A careful study of each case would give the best results.

Dr. Talbot R. Chambers of Jersey City reported two interesting cases. In one he removed in two years 238 needles from different parts of the body.

Dr. Sutphen of Newark said these cases of neurasthenia

were really serious and should not be passed over lightly. Every physician should make his own diagnosis and not be guided by that of others.

Dr. Walter B. Johnson of Paterson, Dr. George H. Balleray of Paterson, and Dr. Elihue Britton Silvers of Rahway discussed the papers. The discussion was closed by Dr. Synnott and Dr. Schauffler.

Chorea and Its Management.—Dr. Thomas P. Trout of Summit read this paper. He considered the seat of the lesion in chorea and its relation to some recently known facts in brain physiology, particularly regarding the muscular movements. The mental symptoms and the etiology (heredity) were also considered. The relationship of chorea to rheumatism and endocarditis was entered upon. Infectious chorea was often accompanied by lesions occurring in other organs of the body than the brain, and he considered the relationship of microorganisms to chorea. Often bacteria became latent and subsequently gave rise to chorea. He concluded his paper by speaking of the management of chorea, the diet, mode of life, and medication.

Dr. Richard Cole Newton of Montclair said that the warships returning from the Orient recently had Japanese servants. Several weeks after leaving the East beriberi broke out among four Japanese and the only possible explanation of this was that it was a latent affection; it resembled in many respects chorea and was supposed to come from eating rice in a peculiar condition. It was also said to be due to an excess of carbohydrates in the diet.

Dr. Henry L. Coit of Newark reported a case of intractable chorea in which death seemed imminent; the situation was extreme and so serious that resort was made to bromides, hyocine, and other nerve sedatives. Somebody suggested the use of apomorphine with the best of results. He reported this treatment to show the possibilities of apomorphine in the worse cases of chorea, and when other measures seem to fail.

Dr. Margaret P. Brewster of Grantwood said that many cases of chorea were received at the Presbyterian Hospital, and their experimenting showed that the cases got well with no medication at all in the same time as those that received it.

Dr. George H. Balleray of Paterson, and Dr. Walter B. Johnson of Paterson discussed the paper. The discussion was closed by Dr. Trout.

A Plea for the Use of the Pharmacopœia vs. Proprietary Preparations.—Dr. H. H. Sherk of Camden presented this paper, which was read by Dr. Emma M. Richardson.

Dr. Daniel Strock of Camden, and Dr. Fred Miller Corwin of Bayonne discussed this paper.

Election of Officers.—*President,* Dr. Henry Marcy, Jr., of Riverton; *First Vice-President,* Dr. Edward J. Ill of Newark; *Second Vice-President,* Dr. David St. John of Hackensack; *Third Vice-President,* Dr. Benjamin A. Waddington of Salem; *Corresponding Secretary,* Dr. Daniel Strock; *Recording Secretary,* Dr. Wm. J. Chandler of South Orange; *Treasurer,* Dr. Archibald Mercer of Newark. Next place of meeting, Cape May, during the last week in June.

NEW YORK ACADEMY OF MEDICINE.

Regular Meeting, Held May 24, 1906.

Dr. Charles L. Dana in the Chair.

This meeting was held under the auspices of the section on pediatrics.

Preliminary Report of the Work of the Medical Relief Committee.—Dr. Charles L. Dana announced that committees had been appointed by the counties of Kings, Queens, Nassau, and Richmond and other societies, and it was hoped that they would work with the committee appointed by the academy. When the committee met it was found that King's county had already raised a fund and were working alone. The committees of the Academy of Medicine, the County Medical Society, and Richmond County Medical Society were working together to secure funds for special purposes, the relief of the medical men who had suffered from the recent disaster in San Francisco. Already $6,000 had been raised, and probably $2,000 more, a fairly large sum of money when it was realized what had been done by these men individually. He called attention to the fact that the Association of American Physicians, at its recent meeting in Washington, had appointed a committee who would try to collect books from medical libraries in the different cities, and he said the academy would send 1,000 duplicates of books, besides the duplicates that were to be sold to the Cooper Medical College for the offer made by them, namely, $6,000.

The Health of the New York School Child, from the Point of View of the Department of Health.—Dr. John J. Cronin, Assistant Chief Sanitary Inspector, read this paper. He said that after all the public school child was a very healthy proposition, and just what influence the department might have had in improving living conditions was not always demonstrable. If the rules and regulations of the department were ideally carried out there would necessarily be less contagious illness; and whether it would ever be possible to produce an ideal condition among the inhabitants of this city that self-concern and concern for the members of the family would be paramount to the question of money or business, was a question to be settled before they could determine just what good might really be accomplished. The Department of Education held the Department of Health to the task of preventing as much contagion as was possible from occurring in the children of the public schools; consequently, school inspection was demanded and inaugurated in March, 1897. At the morning inspection the following classes of cases were examined: Those isolated on account of suspected contagion, those who had been absent for several days, and those excluded from schools. The pediculosis cases were easily disposed of by appointing school nurses to treat, advise, and visit the homes of the children to instruct the parents. Now it was rare to find cases with live pediculi in the head. The trachoma cases numbered at first 17,000, and the department was compelled to open an eye hospital and dispensary at Gouverneur Hospital in December, 1902, and also at One Hundred and Eighteenth street and Pleasant avenue. All operations were performed now at the One Hundred and Eighteenth street hospital, only a clinic being run at the other hospital. The number of cases from December, 1902, to March, 1906, treated by operation were 5,039; the number of revisits, 417,184; the number of cases rejected as not contagious, 889, and 74 cases that were not school cases. The number of cases from March, 1904, to May 12, 1906, at One Hundred and Eighteenth street hospital treated by operation, 106 not school cases, 2,955 school cases; the number of revisits, not school cases, 9,161, and 84,953 school cases; number of cases rejected as not contagious, 157 not school cases, 1,188 school cases. The oculists who were assigned to special duty of testing the vision of school children found that about 29 per cent. of them had defects of vision. The following was a brief report on the work performed from March 27, 1905, to March 31, 1906: Number of cases examined, 79,065; cases of bad nutrition, 4,537; of anterior glands, 22,493; of posterior glands, 4,989; of chorea, 1,184; of cardiac disease, 1,332; of pulmonary disease, 885; of skin disease, 1,574; of deformity of spine, 674; of deformity of chest, 500; of deformity of extremities, 663; of defective vision, 24,534; of defective hearing, 1,633; of defective nasal breathing, 8,974; of defective teeth, 29,386; of defective palate, 936; of hypertrophied tonsils,

13,411; of posterior nasal growths, 7,375; of defective mentality, 1,477; of cases where treatment was necessary, 50,913. Dr. Cronin thought that it would be interesting to note whether or not the number of contagious diseases would not diminish if the Department of Health could control the conditions so that adenoids, tonsils, and teeth might be properly attended to before the child was accepted as a member of a school. It would help diphtheria, the mortality of which was now so reduced that its treatment was uninteresting. They should look to reducing the number of cases. He asked why the child population of each tenement house should not be immunized at the time the case reported was attended to; secondary cases in families where there was a case of diphtheria, if the rest of the family were immunized, were so infrequent as to be of no account, .4 per cent. being the actual number. Day after day they found cases of sore throat in classes in which a pupil at home sick with diphtheria had attended; why shouldn't all the children exposed in the schoolroom be immunized? With immunization more generally adopted and faulty throat conditions relieved, the number of cases should be reduced. When it was learned what classroom the sick child attended, fumigation should be performed in this schoolroom on the very day that the knowledge had been obtained.

The Health of School Children.—Dr. Luther H. Gulick, Director of Physical Training, New York Public Schools, read this paper. (See page 121.)

The Physical Care of School Children.—Dr. R. G. Freeman read this paper. (See page 128.)

Mr. William H. Maxwell, Superintendent of Public Schools, said that Dr. Freeman had started out with a somewhat extremely strong statement about the effects of school work upon the health of the children, and he did not attempt to gainsay these statements, but they would have carried stronger conviction if they had been accompanied by the slightest particle of evidence upon which to base them. The Board of Health now excluded children from the public schools if they were the subjects of colds or showed a tendency to eruptions. It was well to mention this in order to emphasize the importance of producing evidence upon which to base criticisms made upon private and public schools. With regard to the matter of loss of sleep, as long as present conditions existed in this city, just so long would the children of New York be deprived of their sleep. He indorsed all that Dr. Freeman had said regarding the food question, and he hoped to see the day when New York City, as Paris now did, would provide a proper meal for these children in the middle of the day. The system of ventilation now in use in the public schools was doing well; no doubt it could be improved upon, and any information would be welcomed that would aid in improving the ventilation. He corrected Dr. Gulick's statement, that 70,000 children could not be accommodated in the schools, and said that these 70,000 children were on part time. As a matter of fact, they had as many seats and desks as children to-day in the schools, but probably on account of the shifting population, the children were not where those seats were, and the seats were not always where the children were. Mr. Maxwell thought it would be a splendid thing if the Academy of Medicine would appoint a committee, the names of the members of which would carry conviction, to investigate the subject of school desks, and tell them the best kind of furniture that would minimize the evil effects which sprang from the furniture now in use. He commended the work the Board of Health was doing, particularly the work done during the past five or six years, but he doubted their ability to do what was now proposed. For instance, the Department of Health proposed to examine every child before it was admitted to school, and no child was to be admitted until it was shown that its physical condition was good. In the fall 75,000 or 100,000 new children were received, many of them just landed from Italy, southern Russia, the Balkan Peninsula, and Asia Minor, and Mr. Maxwell said it would be a good thing to exclude them until they knew they were in good physical condition, but it was very hard to get these children to attend school at all. Their parents were illiterate and had no sense of the value of education. These mothers would welcome nothing more than that their children should be refused schooling. This was one of the small difficulties which the Department of Health would encounter in carrying out the proposition referred to, but Mr. Maxwell assured them that he would aid all he could in the furtherance of their plans to do this. If the health of the school children were to be improved in this city, it required a remedy far more drastic and more radical than anything the Department of Health could do; it meant a radical change in the housing of the population of this great city. Just as long as the tenement houses existed, as at present constructed, just so long would the health of these children suffer, both physically and mentally. No matter how hygienic one made the school premises, the central fact remained, that during the greater part of the twenty-four hours these children were compelled to live under conditions that not only did not foster but precluded good health.

Dr. A. Jacobi believed that plenty of money was to be had. If Mr. Maxwell required 35,000 more seats he could easily obtain them by excluding children under seven years from the schools. No child under this age should be permitted to attend school. He referred to the results of examining 30,000 school children in St. Louis, Mo., by Dr. Potter, where it was found that the best scholars were those with the best physical development, and this applied all over.

Dr. L. Emmett Holt spoke of the vast possibilities that existed in the way of preventive medicine, and the great strides that had been made along this line by Dr. Cronin and Dr. Gulick. The physicians should teach the mothers how to bring up their children in order to produce the best possible physical development. The children should be brought to the physician's office at least twice a year and be subjected to the same careful examination that the children in the public schools of this city received.

Dr. Wm. P. Northrup hoped the Board of Health would take up the matter of teeth examination and give it serious consideration. The department had attended to the eyes, nose, and throats of these children, and equal attention should be paid to the teeth.

Dr. Henry Dwight Chapin said that the physicians of this city agreed that the children in New York City were underdeveloped. This was the fault of bad housing and bad or insufficient food. The bad or insufficient food question could readily be solved, although the question of bad housing could not. The Association for Improving the Condition of the Poor had recently appointed a committee to look into this question and study it carefully. The tenement children were badly fed, and he hoped that this committee would report what proportion of these poorly nourished children was due to actual poverty, and also what proportion was due to ignorance on the part of the parents. Dr. Chapin believed that higher education was also at fault; during the past years the standards of colleges had been greatly raised, and it was in all probability due to the fact that college educators did not distinguish between mere instruction and education. He would like to see all the colleges lower their entrance examination at least one-half. The plan of raising the standards was bad and crowded the children too much during the period of their growth, and did not allow them sufficient time for sleep and meals.

State Medical Licensing Boards.

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE.	NAME AND ADDRESS OF SECRETARY.	PLACE AND DATE OF NEXT EXAMINATION.	
Alabama*	W. H. Sanders, Montgomery.	Montgomery	August 1–6
Arizona*	Ancil Martin, Phoenix.	Phoenix	October 1
Arkansas*	J. P. Runyan, Little Rock.	Little Rock	October 9
California	Chas. L. Tisdale, Alameda.	Los Angeles / San Francisco	Aug. 21
Colorado	S. D. Van Meter, 1723 Tremont Street, Denver.	Denver	October 2
Connecticut*	Chas. A. Tuttle, New Haven.	New Haven	Nov. 13
Delaware	P. W. Tomlinson, Wilmington.	Dover	Dec. 11
Dis. of Col'bia	W. C. Woodward, Washington.	Washington	October 11
Florida*	J. D. Fernandez, Jacksonville.	Jacksonville	October 17
Georgia	E. R. Anthony, Griffin.	Atlanta	October 9
Idaho	J. L. Conant, Jr., Genesee.	Lewiston	October 2
Illinois	J. A. Egan, Springfield.	Chicago	October 17
Indiana	W. T. Gott, 120 State House, Indianapolis.	Indianapolis	October 23
Iowa	J. F. Kennedy, Des Moines.	Des Moines	Sept. —
Kansas	T. E. Raines, Concordia.	Topeka	October 9
Kentucky*	J. N. McCormack, Bowling Green.	Louisville	October 23
Louisiana	F. A. La Rue, 624 Gravier St., New Orleans.	New Orleans	October 19
Maine	Wm. J. Maybury, Saco.	Portland	Nov. 13
Maryland	J. McP. Scott, Hagerstown.	Baltimore	Dec. 12
Massachusetts*	E. B. Harvey, State House, Boston.	Boston	Sept. 11
Michigan	B. D. Harison, 205 Whitney Building, Detroit.	Lansing	October 9
Minnesota	O. E. Linjer, 24 South Fourth Street, Minneapolis.	St. Paul	October 2
Mississippi	J. F. Hunter, Jackson.	Jackson	October 9
Missouri	J. A. B. Adcock, Warrensburg.	St. Louis	August 8
Montana*	Wm. C. Riddell, Helena.	Helena	October 2
Nebraska	Geo. H. Brash, Beatrice.	Lincoln	August 8

* No reciprocity recognized by these States.

† Applicants should in every case write to the secretary for latest details regarding the examination in any particular State.

Requirements of the State Examining Boards.—1. The following States require both a diploma and an examination: Arizona, California, Connecticut, Delaware, District of Columbia, Florida, Georgia, Idaho, Illinois, Indiana, Iowa, Kansas, Kentucky, Louisiana, Maine, Maryland, Michigan, Minnesota, Montana, Nebraska, New Hampshire, New Jersey, New York, North Carolina, North Dakota, Ohio, Oklahoma, Pennsylvania, South Carolina, South Dakota, Utah, Vermont, Virginia, Washington, Wisconsin, and Wyoming.

2. The following States require an examination only: Alabama, Arkansas, Massachusetts, Mississippi, Missouri, Oregon, Rhode Island, Tennessee, Texas, and West Virginia.

3. The following States require either a diploma or an examination: Colorado, Indian Territory, Nevada, and New Mexico.

Oregon.—At the examination held in May, there were 41 applicants; of this number only 18 passed.

Illinois.—This State is no longer a member of the American Confederation of Reciprocating Examining and Licensing Boards, having withdrawn at the June meeting. At the same time it decided that after January 1, 1907, it will not reciprocate with any State board which exacts an examination of a candidate who has already passed an examination before another board.

North Carolina still declines to consider the matter of reciprocity. It is of the opinion that is not so much difference between the technical qualifications required by the examining boards of the different States as there is in the minimum standard of the entrance examinations in the different medical schools.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending July 21, 1906.

	Cases	Deaths
Tuberculosis Pulmonalis	393	182
Diphtheria	206	28
Measles	268	8
Scarlet Fever	72	6
Smallpox	—	—
Varicella	29	—
Typhoid Fever	60	17
Whooping Cough	59	7
Cerebrospinal Meningitis	3	12
Malarial Fever	.....	.....
Totals	1,090	260

Osteomalacia Cured by Causing Atrophy of the Ovaries by the X-Rays.—Ascarelli, since it has been experimentally established that the ovaries may be made to undergo atrophy by the use of the *x*-rays, has attempted to substitute radiotherapeutics for ovariectomy in the treatment of severe cases of osetomalacia. In one case treated by this method, after two months the patient commenced to improve, while menstruation became abundant, irregular, and painful. After five months the patient was entirely cured and menstruation had disappeared. Five months had elapsed since then and there were no symptoms of the disease, and the menstruation had not reappeared.—*La Riforma Medica.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon General, Public Health and Marine Hospital Service for the week ending July 21, 1906.

DIAGNOSTIC FEATURES OF SURGICAL DISEASES ATTENDED WITH ACUTE JAUNDICE.

BY A. A. BERG, M.D.,

NEW YORK.

ADJUNCT SURGEON, MT. SINAI HOSPITAL

THE staining of the skin and mucous membranes with the coloring matter of the bile or its derivatives results either when the bile ducts are obstructed or when there is an excessive destruction of red blood cells in the liver. In the former instance the bile stagnates in the biliary capillaries of the liver, when it is reabsorbed into the blood and so gives rise to obstructive jaundice, and in the latter case the liver elaborates the hemoglobin that is set free by the excessive hemolysis into bile pigments, which, being secreted into the biliary capillaries in greater amount than can be passed on by them into the larger bile ducts, is partly resorbed into the circulation and thus occasions hemohepatogenous jaundice.

It was formerly considered that the presence of the salts of the biliary acids in the urine which occurs with obstructive jaundice distinguished this variety of icterus from the hemohepatogenous type. But as not all the cases of the former are attended with these salts in the urine, this method of their differentiation does not hold good.

Simple as is this pathogenesis of icterus, so complex and varied are the diseases that provoke it. My intent this evening is to consider from a diagnostic standpoint the more important surgical diseases, of which one of the symptoms is an acute jaundice.

It is quite commonly considered that all cases of liver abscess are accompanied by jaundice, and yet in practise this is not found to be the case. The writer is often asked by junior members of the house staff to explain the absence of jaundice in a case that has been diagnosed as one of liver abscess, and only recently he was told in the consulting room by a colleague that liver abscess had been excluded, firstly, because the patient was not jaundiced, and, secondly, because liver suppuration in this climate is very infrequent. Both of these objections fell to the ground when aspiration of the liver yielded pus.

Suppuration within the liver occurs in two forms, the single tropical abscess and the acute single or multiple abscesses. The former is attended with jaundice only when the abscess occludes a large number of the smaller ducts within the liver or compresses the extrahepatic portion of the hepatic or common bils ducts. The latter is attended with jaundice when either of the above conditions prevail or when the bacteria which occasion the hepatic suppuration are very virulent and cause a marked degree of hemolysis. The intensity of the jaundice in any particular case depends upon the amount of compression or occlusion of the bile ducts and upon the degree of hemolysis.

The diagnosis of liver suppuration does not rest upon the presence or absence of icterus. The existence of a cause for this affection such as suppuration or ulceration in the abdomen within the area drained by the portal vein and its tributaries, *e.g.* appendicitis; cholecystitis, gastric, duodenal, intestinal, or colonic ulceration, hemorrhoids or trauma over the liver, together with the physical signs of enlarged liver and pain and tenderness over the liver and temperature elevations are the important data upon which we rely to establish a diagnosis of this condition.

As regards enlargement of the liver, it is to be remembered that enlargement upward and backward with consequent elevation of the diaphragm and more or less compression of the base of the right lung, and enlargement laterally with consequent widening of the lower intercostal spaces and bulging outward of the lower ribs are equally frequent with enlargement directly downward, and yet in our routine physical examination how seldom is it that we determine by percussion and auscultation the upper posterior limits of this organ? Similarly the determination of the size of the left lobe is usually overlooked, and yet this may be the only portion of the organ that is enlarged. In some cases an enlarged left lobe may extend over into the left hypochondrium, where it may be mistaken for an enlarged spleen. The differentiation, however, is readily made if we remember that the latter organ has a deep notch on its anterior border.

It is to be noted that the best way to elicit liver tenderness is to suddenly compress the lower ribs with the flat of the hand. As the greatest tenderness exists at that site at which the abscess is most superficial, it is important in every case to ascertain by pressure with the finger tip the area of most acute tenderness, for it is at this site that exploratory aspiration or incision should be made.

The presence of pus can thus with fair certainty be diagnosticated from the clinical history and the physical signs, but it can only be positively confirmed by aspiration or exploratory incision. When the suspected abscess is in the lateral or posterior portions of the right lobe we may resort to exploratory aspiration, using therefor a fine calibered long needle and making the puncture through the intercostal space at the site of greatest tenderness. But when the suspected abscess is in the median portions of the right lobe or in the left lobe it is better to resort to exploratory incision, because with the needle we may injure some one of the adjoining hollow or vascular organs.

Some months ago I had the privilege of pre-

senting to you a case of acute infectious cholangitis with jaundice. The infrequency of these cases will justify me in rapidly reviewing the clinical history at this time.

Louis S., thirty-four years old, was admitted to the service of Dr. Gerster at Mt. Sinai Hospital on July 27, 1904. His family history was negative. He stated that from his tenth year of life he had had at periods of three to five years attacks that were similar to the present illness. These attacks were characterized by pain in the epigastrium and right hypochondrium; in some he had chills and in some he was jaundiced. Each attack lasted for four or five weeks, and between them he felt perfectly well. His bowels were always constipated and had to be moved by enemata.

His present illness was of seven days' duration. Its onset was sudden with chill and marked by severe pain in the epigastrium and right hypochondrium. He vomited several times. Since then he became jaundiced, his stools being very light, like coagulated milk, and his urine dark brown; he had two or three chills a day, and the pain continued.

On admission he had a severe shaking chill, his temperature was 102°, pulse 98, and respirations 27. He was markedly icteric; his lungs and heart were normal; his abdominal wall was rigid, especially in the right hypochondrium, where there was marked tenderness. The liver was enlarged, the flatness extending from the sixth rib to two fingers' breadth below the costal border. In the gall-bladder region was a tumor that was tender, fused with the liver above, and moved with respiration. The spleen was not enlarged. There was no free fluid in the abdominal cavity. The leucocytes numbered 21,000 to the cubic millimeter.

The previous history of similar attacks of pain and jaundice, though very indefinite and vague, prompted me to diagnosticate biliary lithiasis with acute cholangitis. I immediately opened the abdomen by vertical incision in the right hypochondrium through the fibers of the right rectus muscle. The liver was found to be enlarged. The tumor that was felt prior to operation was found to be an enlarged, distended gall-bladder that was dark red in color, and to it the omentum and intestines were adherent. There were no stones in the gall-bladder or bile ducts. The common bile, cystic and hepatic ducts were considerably thickened and felt like rigid cords of lead-pencil thickness. The contents of the gall-bladder could not be emptied into the ducts by pressure. The gall-bladder was aspirated, about 100 cubic centimeters of black bile being withdrawn. A culture was at once made from it. The viscus was then incised and its interior inspected and palpated; the mucous membrane was dark red in color, and there were no calculi to be felt. The gall-bladder was drained by large-sized tube and the rest of the abdomen closed by layer sutures. The day after the operation the temperature rose to 104°, but thereafter there was a gradual defervescence. The jaundice gradually disappeared, the patient making an uninterrupted recovery. The bile lost its black color after the first week and became golden brown in color. The bile on culture was reported to contain in pure growth the bacillus of Friedlander. A blood culture taken on the third day after operation remained sterile. Widal reaction of the serum was negative.

Another case of somewhat similar character that I operated upon some three years ago I reported in conjunction with my colleague, Dr. Libman, whose excellent bacteriological investigations in connection therewith have given to it a classical place in medical literature. The history of this patient was in brief as follows:

Charles I., thirty-three years of age, I saw with Dr. Hubbard of Boro Park, on August 29, 1901. His previous history was practically negative. Eight days prior to the day I first saw him he was taken suddenly ill with nausea, vomiting, and prostration. His temperature, taken by mouth, at that time was 100°. There was abdominal distention and pain in the epigastrium. He remained in bed only two days, but felt too weak to return to his work. On August 28, 1901, he was suddenly seized with severe colicky pain located in the epigastrium and right hypochondrium, vomiting, and constipation, his mouth temperature rising to 104.2°. The following morning the temperature fell to 101°, but in the evening it rose again to 103°.

On admission to the hospital August 3, 1902, his skin was subicteric, the temperature was 105.4°, pulse 112, respiration 26. The abdominal wall was rigid, particularly on the right side. The liver was slightly enlarged, and below the costal margin in the right hypochondrium was to be felt a very tender mass about the size of a lemon, and connected with the liver. The spleen was enlarged to percussion, but there was no roseola, no Widal reaction in the blood serum, and no Ehrlich reaction in the urine. Leucocytes numbered 15,000 to the cubic millimeter.

The case appeared to me to be one of liver abscess or acute suppurative cholecystitis, and, accordingly, on September 1 I opened the abdomen in the right hypochondrium through the fibers of the right rectus muscle. The mass which had been felt was found to represent a tongue-shaped lobe of the liver, *i.e.* the so-called Riedel's lobe, overlying a distended gall-bladder. On the surface of Riedel's lobe there was some inflammatory fibrin. The liver substance was not indurated or softened. The gall-bladder felt moderately tense; its contents could not be expressed through the ducts into the duodenum. The cystic and common bile ducts felt thickened, but contained no stones. The gall-bladder was aspirated and dark, thick bile obtained. The liver was then aspirated in several directions with negative result. As there seemed to me to be no indication for drainage of the gall-bladder and bile ducts I closed the abdominal wound. After the operation the temperature varied between 103°-106°; intense jaundice was established with marked cerebral symptoms. On September 9 incessant vomiting developed, and on the following day the patient died.

The fluid aspirated from the gall-bladder contained in pure culture the paracolon bacillus. The blood and urine likewise contained the same organism in pure culture. On September 8 a positive Widal reaction was reported in a dilution of 1-200. A very limited autopsy showed an acute parenchymatous degeneration of all the viscera, and in the intestines typhoid ulcerations, some healed and some in the process of healing.

If we summarize these two cases we will find that in both the onset of the symptoms was acute; in one of the cases with repeated chills, with pain in the epigastrium and right hypochondrium, high fever of remittent type, nausea, vomiting, and increasing jaundice. On examination both cases showed an enlarged liver, a tender and enlarged gall-bladder, and a moderately increased

leucocytosis. On opening the abdomen the liver in both cases was found to be enlarged, and in one case it was covered with patches of fibrin; the gall-bladder was distended, its contents could not be expressed through the ducts into the duodenum, and the extrahepatic bile ducts were thickened and rigid and enlarged. The interior of the gall-bladder was dark red and congested in the case in which this viscus was opened, the walls were friable, and the contained bile was black and viscid. There were no stones in the gall-bladder or ducts. Aspiration revealed no pus in the liver. In the fatal case autopsy showed acute degeneration of the viscera and typhoid ulcerations and scars in the intestines. The bile on culture was shown to contain a pure culture of the Friedlander bacillus in the one case and a pure culture of the paracolon bacillus in the other. In the former blood culture was sterile; in the latter it, too, showed a pure growth of the paracolon organism.

The enlarged liver, the distended, tender gall-bladder, the thickened swollen ducts, and the infected dark viscid bile, together with acute onset of high fever, nausea, vomiting, pain in the epigastric and right hypochondriac regions, and jaundice, indicate in both of these cases an acute infectious cholangitis.

How shall we explain the method of this infection of the ducts? The liver, as we know, receives, through the portal vein and its tributaries, the bacteria which are resident in the intestinal tract, and through the hepatic artery bacteria which are resident in the general blood stream. These bacteria it tends to destroy. If, however, they are very numerous or if the liver cells are diseased and therefore fail to dispose of them, then the bacteria escape with the bile into the biliary capillaries, ducts, and gall-bladder; these viscera they infect, and in them they can occasion an acute cholangitis. In one of our two cases the infection of the biliary capillaries, ducts, and gall-bladder followed an acute, systemic infection with the paracolon bacillus, while in the latter the infection of the ducts with the Friedlander bacillus was probably carried to the liver from the intestinal tract by the portal vein.

I regret very much that I did not drain the biliary ducts in the first of the two cases as I did in the second one, for the carrying away of the infected bile might have had a favorable influence toward helping the patient to eliminate the systemic infection. The truth of the matter is that we surgeons did not in those days appreciate that acute infectious cholangitis could occur as a primary infection without the presence of gallstones, and, finding no stones in the ducts or gall-bladder in this case, and no gross pathological changes, I decided not to drain. To-day it is far different. We find, upon opening the abdomen, the changes in the liver and ducts above mentioned, whether or not there are stones in the biliary apparatus, we establish free drainage of the gall-bladder and ducts, to which procedure the happy outcome of my second case was undoubtedly due.

It is to be noted that such acute infective cholangitis can also occur in any of the acute infectious diseases, especially typhoid and pneumonia, and it is still to be decided whether the malignant jaundice that accompanies some of these diseases, especially typhoid, could not be favorably influenced by drainage of the bile ducts and gall-bladder.

Diagnostically these cases of primary acute infectious cholangitis may offer the greatest difficulty, for the pain in the epigastrium and right hypochondrium and the jaundice are thoroughly suggestive of gallstone disease, to which the cholangitis is secondary, while the enlarged tender liver, moderately increased leucocytosis, and fever and chills speak for miliary abscess of the liver.

It will aid us some if we remember that in gallstone disease of long standing, for it is especially the long-standing cases of this affection that are complicated by cholangitis, the gall-bladder is most likely contracted and small and not palpable on account of cicatricial contraction of the viscus from repeated previous attacks of cholecystitis, whereas in the primary acute infectious cholangitis cases the gall-bladder is distended, enlarged, and readily palpable. The history of previous attacks of biliary colic with the passage of stones with the stools of course speaks strongly in favor of the cholangitis being secondary to preexisting gallstone disease. Miliary abscesses of the liver always follow suppuration or ulceration of some one of the intraperitoneal organs, and the history or clinical evidences of such affection is, of course, strongly suggestive of such miliary abscesses in the liver. We must not forget, however, that acute infectious cholangitis may secondarily occasion miliary abscesses of the liver, and, vice versa, that miliary abscesses of the liver may cause an acute infectious cholangitis.

The labors of Kehr, Riedel, Courvoisier, and others have taught us the meaning of acutely developing jaundice in gallstone disease. With an attack of biliary colic jaundice will develop when one or more calculi enter into the common bile duct and more or less completely occlude its lumen. If the calculi do not enter into the choledochus there will be no jaundice. This occurrence of icterus after an attack of colicky pain which is located in the right hypochrondrium, and radiates to the back and right shoulder at once enables us in the vast majority of cases to diagnosticate biliary lithiasis. But how different it is when, because the stones do not leave the gall-bladder, the patient suffers the pain, but does not become jaundiced. In such cases we often experience the greatest difficulty in determining the cause of the pain; for pyloric and duodenal ulcer, pancreatic stone, aseptic renal stone, unilateral chronic nephritis, and even chronic appendicitis, all can provoke pain that is located and referred to the same regions as is that which attends biliary lithiasis.

A man whom I saw some two years ago with my friend Dr. Rieser affords an instance of the difficulty that is sometimes experienced by even the most expert in making a diagnosis in such cases. Max L., a barber twenty-seven years old, with an entirely negative family and previous personal history, was suddenly taken with pain in the right iliac region. The pain was severe and a few days after its onset it moved upward to the liver region. Subsequently the pain came on in attacks; it started in the region of the liver and passed upward to the sternum, also around the side to the back and upward, to the left shoulder. With the pain the patient felt nauseated, but did not vomit. The conjunctivæ, he says, were yellow, but this had passed away. There was no change in the stools or skin. He had lost ten pounds in weight and considerable strength during the nine weeks of his illness.

On physical examination there was a very slight subjunctival icterus. His lungs, heart, and

liver were normal. There was no abdominal rigidity; no abdominal tenderness except on deep palpation in the right iliac region. There was no mass in the gall-bladder region.

The only symptom, then, was the pain, and, in spite of most careful observation by his family physician, who summoned to his aid some of the best and most expert diagnosticians in the city, the cause of the pain remained in doubt. Exploratory laparotomy revealed an open pyloric ulcer, for the relief of which I established a posterior gastroenterostomy with complete relief of the patient's suffering and entire cure of the ulcer.

In such cases we will be most successful in diagnosis if in a systematic fashion we set about excluding one thing after the other. An examination of the chemical composition of the gastric juice and a determination of the gastric motility will afford valuable data as to the presence of pyloric or duodenal ulcer; for if there is a constant hyperacidity, and if the pain is worse immediately after eating, and if there is a cutaneous head zone of pain corresponding to that provoked by pyloric or duodenal ulcer, and if there are eructations of acid material, we have considerable evidence in favor of this condition. The occurrence of slight subconpunctival icterus, as in the case just narrated, is no argument against gastric ulcer, for this may be due to peripyloritic adhesions which kink the common bile duct, or, in the case of duodenal ulcer, to catarrhal swelling of the papilla of Vater.

Cystoscopic examination of the vesical ureteral orifices and separation of the urines with the ureteral catheters with careful chemical and microscopical examinations of the individual urines combined with *x*-ray examination will throw considerable light upon those obscure diseases of the kidney, such as aseptic stone, chonic unilateral nephritis, and early tuberculosis, that provoke pain in the right hypochondrium and back.

How we welcome in these doubtful cases an acute jaundice developing after an attack of pain! The uncertainty and doubt in which we have been groping are at once replaced by a flood of light. The diagnosis is now readily established, and if later on stones are found in the stools the diagnosis is only made more certain.

But, after all, our uncertainty of diagnosis in such cases need not weigh upon us too heavily. As Wm. Mayo has said, "The essential point to determine in these cases is whether they are to be treated medically or surgically." And if a patient with continuous or colicky pain in the right hypochondrium is not relieved by a well-instituted and carefully conducted internal treatment with dietary regulations, and is rendered unable to attend to his customary duties by such pain, it becomes the imperative duty of his attendant to advise exploratory diagnostic laparotomy.

Acute inflammations and distention of the gall-bladder secondary to calculous disease is attended with jaundice when the distended enlarged viscus compresses the common bile duct, or when there is also present a complicating cholangitis. The icterus in these cases is rarely deep. The distended enlarged gall-bladder, without any enlargement of the liver and spleen, distinguishes most of the cases of jaundice due to compression of the choledochus by the gall-bladder from the cases of jaundice due to obstruction of the common bile duct by a calculus; for, according to Courvoisier's law, the gall-bladder in these latter cases is contracted and nonpalpable, and the liver and spleen are enlarged. And similarly the presence of an enlarged tender gall-bladder distinguishes the cases of acute jaundice due to cholangitis that originates from a cholecystitis, from those cases of cholangitis that take their starting point from an impacted stone in the choledochus.

We are often called upon to decide in a case of acute jaundice following an attack of biliary colic whether the stone has passed or has remained impacted in the duct. The finding of stones in the stools does not answer the query, for a number of stones may have passed out of the gall-bladder into the common duct, some of which may have passed through it, and some of which may have become impacted in the duct. There is no way in which we can tell, off hand, whether all of the stones have passed. Such cases must always be observed at least for four weeks before we come to any conclusion. If, after this period, the jaundice persists, no matter whether it is constant in intensity, we may assume that the stones are impacted in the choledochus. I remember the case of a woman from whom about two years ago I removed about fifty stones from the common bile and hepatic ducts, and from the hepatic ducts of the liver. I established drainage of the common hepatic duct, and for about six weeks small calculi that came down from the hepatic ducts in the liver were continuously discharged through the drainage tube. When for two weeks no further calculi appeared I removed the drainage tube and allowed the wound to heal. She remained well for about a year, and then had an attack of biliary colic, followed by moderate jaundice. She was naturally much concerned as to whether she would have to be reoperated. After a week's time the jaundice entirely disappeared, and, though there have been one or two recurrences of pain, there has been no further jaundice, so that I hope she has at last eliminated all the calculi from her liver.

This case is of deep interest as showing the possibilities of a primary formation of calculi in the biliary ducts of the liver, for though her gall-bladder was absolutely free of calculi and was in every respect normal, her intra- and extrahepatic biliary ducts were simply choked with stones.

Syphiloma or gumma of the liver when they break down are sometimes attended with acutely developing jaundice. This, together with fever and the presence of a painful tumor in the gall-bladder region, are strongly suggestive of biliary lithiasis with acute cholecystitis. Careful examination, however, will reveal that there are multiple nodules in the liver, that the liver edge is thick and rounded, that there are other evidences of syphilis in the skin, mucous membranes, and bones, and a little cross-questioning will usually elicit the history of the initial primary lesion of syphilitic disease.

I have thus far entered into the clinical aspects and diagnostic features of the more important acute surgical affections of the liver and gall-bladder and adjoining organs that have as one of their symptoms an acutely developing icterus. It was stated at the beginning of this paper that icterus also follows when from any cause there is an increased hemolysis. Probably the most frequent surgical causes of such an increased destruction of the red blood cells are bacterial infections and the administration of ether or chloroform. This explains the jaundice that occurs in acute osteomyelitis, in diffuse septic peritonitis,

in acute appendicitis, etc. The clinical evidences afforded by the primary malady usually enable us to recognize it, and to account for the jaundice. Such icterus may be of the deepest grade. Clinically it has significance only in so far as it bears evidence of the severity of the infectious process.

The statement I made at the beginning of this paper, that the pathogenesis of jaundice is simple, but that the diseases that provoke it are varied and multiple is seen to be true from the remarks I have made. And yet I have considered only the most common of the surgical diseases that are attended with this symptom. What a number of possible diseases enter our mind as we approach the bedside of an acutely jaundiced patient!

If we are to differentiate successfully between them and establish the correct diagnosis, we must elicit a careful anamnesis, make a thorough physical examination, and then carefully analyze the data we have obtained.

923 Madison Avenue.

THE THERAPEUTIC ACTION OF SPLENIC EXTRACT IN MALARIAL INFECTIONS.

By CHARLES RAYMOND CARPENTER, M.D.,

Leavenworth, Kansas

Something over six years ago an article was published by the writer in the Medical Record,* in which attention was called to the therapeutic effects of the substance or the extract of the spleen. It was particularly recommended in typhoid fever, although it was stated that the number of cases treated to that date had been too small to warrant a final conclusion as to its value. During the time intervening between that date and the present, the writer has used the remedy spoken of almost constantly, with two results.

The first of these is to prove that given internally in typhoid fever, while it seems to influence the temperature favorably, it more than offsets this by increasing the diarrhea, and its final effect is therefore not favorable. This fact is the more notable when we take into consideration the other fact brought out by some of the cases cited below, that the remedy frequently controls diarrhea from other causes.

But its evident control over temperature led to its use in malarial infections, and, with the second of the two results already mentioned, the most surprising and complete success. In more than six-years' continuous experience, and the treatment of hundreds of cases of malarial infections of all types, both simple and complicated by all sorts of conditions, not a single case has been met with which did not yield to this remedy.

Every physician who has practised in the malarial districts of the United States knows what this means. There is not a pathological condition known to afflict the human race in these same localities that may not be, and is not, continually liable to be complicated by this ever-present pest; and always with the result of exaggerating the difficulties of the case, and the instant demand that quinine, or some equally effective remedy, be administered.

Many substitutes have been recommended and used, but we have always come back to quinine. And many will say immediately, as they see or hear the title of this paper, "What, another? Excuse me, I do not care to try any more substitutes!" Indeed they cannot well be blamed, for it must be admitted that they have some excuse for their prejudice. There are many others, however, who recognize that quinine is at all times a disagreeable remedy to take, owing to its profound influence upon the nervous system when given in doses large enough to destroy the life cycle of the plasmodium. And they also recognize the fact that its effect upon the organism is not always of a transitory character. Many have claimed that its effect was transitory, but the evidence of accumulated cases has now piled up so high that it would seem difficult for anyone now to deny that the deleterious effect of quinine is frequently permanent, or difficult to remove.

But even when this effect is of such a character that it may properly be called transitory, it is frequently so disagreeable, not to say alarming, that it is far better eliminated when possible. What is the use of producing disturbances of vision, or blindness, or deafness, or even tinnitus aurium, or vertigo, or headache, in order to cure your patient, if you can just as easily and as certainly do so without those inconveniences?

Quinine is an absolutely reliable remedy for malarial infections. No one will ever deny that; and it has occupied a position in the history of medicine, the importance of which is perhaps not exceeded by any other single remedy in the pharmacopœia. But it is here affirmed, on the warrant of six and a half years' continuous use in hundreds of cases in every phase of general practice, that the extract of the spleen is an equally reliable remedy in the treatment of malarial infections. And furthermore, that in all but excessive doses, it is devoid of all the unpleasant and injurious effects that have been attributed to quinine, whether rightly so or not.

This is a broad statement; but if a remedy cannot show what it is worth in six and a half years of continuous use by one in active general practice, in a locality where malarial infections are always in evidence and to be reckoned with, it seems reasonable to infer that there is small probability of its ever doing so. Splenic extract, in the hands of the writer, has shown itself to be a real remedy for malarial infections.

Of course there are certain conditions, as in the case of perhaps all remedies to a greater or less extent, that make for success, and which if neglected may as easily contribute to failure in its use. Being an organic preparation, care is necessary that it do not spoil in the hands of either the druggist or the patient. This difficulty is very easily overcome if the condition which contributes most to its deterioration is borne in mind. This is the absorption of moisture, even in a slight degree. Careful laboratory methods have enabled manufacturers now to produce a preparation that will keep in almost any ordinary temperature. But after the original package has been opened, care is necessary in handling the remedy to see that it is not allowed to remain long in contact with the air.

Some druggists are strangely indifferent, and need to be admonished that it is necessary to keep the bottle tightly corked while it is sitting on their shelves, or it soon loses its therapeutic value.

Physicians should never prescribe it without keeping this practical point in mind. Be sure in the first place that your druggist understands how to preserve the therapeutic properties of the extract, and in the second place, be sure to see that it is dispensed in such a manner that those properties will be preserved while in the hands of the patient.

The best and safest way to prescribe it is in powdered form, enclosed in capsules. Even when pre-

*"Splenic Extract and the Splenic Function," Medical Record, February 17, 1900.

scribed for a patient who cannot swallow capsules, as in the case of babies or small children, it is best so to prescribe it, for it can always be removed from the capsule when given, if necessary, or poured directly from the capsule upon the tongue of the patient. When prescribed in this manner, the gelatine coating is practically a guarantee that no moisture will be absorbed by the remedy from the atmosphere.

Tablets are very convenient, and so long as they are dispensed in the original package, and the patient understands the importance of keeping the bottle tightly corked, no trouble need be anticipated. But if, as is frequently the case, it is desired to dispense them in small quantities, the druggist puts them in the usual loosely closed pill box, they are kept in the sick room for a day or two, absorb moisture, and turn dark. The patient continues to take them, but does not improve or gets worse. The doctor loses patience, prescribes quinine, and says organotherapy is merely a fad anyhow, if not a fraud.

The preparation should always retain its light brownish-gray color, and should have a faint, sweetish, not unpleasant odor. The taste is also sweetish, not unpleasant, and children do not object to it. Any preparation which has a disgusting, or in any degree unpleasant odor, cannot be said to fulfill the conditions which contribute to success in its use.

The only other condition which, provided the preparation used is of proper quality, blocks the way to success in the treatment of malarial infections with splenic extract, is the one which not infrequently prevents good effects also from the administration of quinine. This is a reduced proportion of hemoglobin in the blood.

This is easy to understand, if we consider that, as seems likely, the leucocytes produced in the spleen, and which constitute, together with those produced by the glandular systems, the defensive element of the blood against disease, are elaborated from materials furnished by the red corpuscles, which are found in the spleen in all stages of disintegration and destruction. The findings of experimental physiology all point very suggestively to the probability that the spleen is one of the most important heating plants of the body, with the red corpuscles acting as the fuel. And now we have presented to us from the therapeutic side of the subject a corroboration not only of this, but also of the theory that the red corpuscles are the building materials from which are made the leucocytes that come from the spleen. For one of the most essential ingredients of the red corpuscles, that upon which depends, we are told, their oxygen-carrying power, is the hemoglobin. But we find that when this hemoglobin is very much reduced, the spleen is powerless to produce the usual output of leucocytes, and fails to do so, no matter how much we stimulate it by supplying its own elements and active principles. That is to say, it fails to produce its known therapeutic effect under these circumstances. On the contrary, as soon as we begin to reproduce the hemoglobin by giving hematinics, the usual therapeutic dose of splenic extract produces the desired effect. The spleen responds; the malarial infection disappears, quietly, without shock or disturbance of any kind.

Many have thought that the therapeutic effects of glandular extracts were due to a common principle found in them all, in short to nuclein, or nucleinic acid, and have advocated giving a preparation of nuclein made from some easily procurable substance, such as yeast.

The chemistry of the nucleins is not well understood, but it is a vital mistake to suppose that any one of them can do the work of all. If organotherapy has shown anything, it has shown that the substance or extracts of the different glands of the animal body differ as sharply in their therapeutic action as do the extracts made from the different plants of the vegetable world. This fact leads naturally up to some strange and far-reaching questions.

How far may we account for the physiological and therapeutic effect of some drugs by the fact that they stimulate, or depress, or restore, or modify, the functions of those organs of the body which we are just now discovering have the power when given internally to produce similar effects on the organism? Is it possible that the developments of modern organotherapy have unveiled to our eyes that mysterious *vis medicatrix naturæ,* of which the writers of a century gone by had much to say, and which, in all times, the true physician has been obliged to admit is his last and greatest resource?

We are in the habit of saying that quinine has a specific action in malarial infections. How much of that action is due to its power of restoring simply the function of the spleen, which the familiar symptoms of the disease indicate must be impaired? True, it has a certain germicidal action, which may easily be demonstrated outside the body, but if its specific effect in malarial infections was dependent on this action alone, would it not be reasonable to suppose that other germicides of equal or greater power would have at least as good an effect in the same class of infections? Certainly it would seem so. But we know that they do not.

You may saturate the body with mercury, or iodine, or sulphur, or carbolic acid, or alcohol, or any of their compounds or derivatives; you may saturate the body to the last degree with any known antiseptic, no matter what its power, but you cannot produce the well-known specific effect of quinine in malarial infections. The best substitutes we have had for quinine, such as berberine, arsenic, and iodine, while they undoubtedly have more or less germicidal power, are not, with the exception of the last, usually classed as germicides. And this there is good reason for believing produces its effect in malarial infections more by its powerfully stimulating action on the lymphatic glands of the body than by any directly germicidal action. This, by the way, should be borne in mind while considering some of the remarks further on, relative to glandular extracts. Germicides, as such, are not notable for their beneficial action in malarial infections. On the contrary, splenic extract, which has no proved germicidal action outside the body, produces identically the beneficial effects of quinine in these infections, and without any of its bad effects.

One of the most notable things that follow the administration of quinine is the rapid reduction in the size of the spleen. We say habitually that this is one of the effects of quinine; and so it is in a way, but the same result follows the administration of splenic extract.

Does it not seem probable, therefore, that the effect of the plasmodium upon gaining entrance to the circulation, is to inhibit the function of the spleen? At the same time, it rapidly destroys the red corpuscles, which constitute the blood fuel, as well as the material necessary for building the leucocytes. The organ seems paralyzed. A steady stream of materials is pouring into it which it is not able to use. Its contractile tissues relax; it becomes

turgid and swollen. It is powerless to produce fresh leucocytes, and the old ones are exhausted, or dying, or dead. Examine the blood under the microscope at this time, and the leucocytes will be found spread out into ragged irregular sheets, or masses, filled with detritus, and disintegrating.

But the oxidizing power of the spleen does not seem to be inhibited; and the inhibition of the corpuscle-building function leaves a large quantity of oxidizable material on hand, which is constantly increasing. Oxidation goes on with far greater rapidity than before, in spite of the presence of the plasmodium. The blood, heated to an unusual degree, carries its high temperature to every part of the body, raising its temperature also to a corresponding degree. Is it possible we have here the true pathology of the fever temperature? The question is worth considering.

Let us carry the theory through to its legitimate conclusion. Suddenly a new influence is felt in the blood. It may be quinine, or it may be splenic extract. As it passes into the spleen, that organ is quickened into new life. Its activity returns. It begins to pour into the blood stream a volume of fresh, active leucocytes, and like a reinforcement of fresh troops on a field of battle, it results in saving the day. The enemy is driven back from the citadel of the body. But this is not all. The contractile fibers which have been relaxed and powerless, are renewed in strength and the organ begins to contract upon itself; its size is steadily reduced. The renewed activity in the cell-making function produces immediate inroads upon the oxidizable material which the organ has been struggling to dispose of. The fuel being reduced in quantity, the conflagration is checked. Hyperoxidation ceases; the temperature of the blood falls, and therefore the temperature of the body returns to the normal. Whether the true pathology of the fever temperature is here given or not, the extract of the spleen therapeutically controls almost absolutely the body temperature during the febrile condition.

If it be true that the important function of the spleen is to furnish the blood with elements which constitute a physiological defense of the body against infection by the malarial plasmodium, then it is but a logical step to inquire, "Why will it not furnish the same protection against other infections?"

As a matter of fact, investigation is showing that it is of decided benefit in other conditions having an infectious origin. Time alone can tell in how many. The natural inference from what has gone before would be that it should actively combat all infections. But we find that this is not the case; and that infections from the standpoint from which we are now viewing them, are divided into at least two quite distinct classes. Those that attack the life forces through the circulation, and those that do so through the various glandular systems. In the former class splenic extract is a sovereign remedy; in the latter its effect is not so marked, though in many cases beneficial. These things seem to argue that the glandular organs of the body exercise a supplementary function to the spleen in its defense of the life forces. Probably none of the glands are more important in this regard than those of the lymphatic system. It will be remembered that these glands, although of small size, multiply in number, and widely scattered through the body, occupy a position upon the lymph channels relatively the same as that the spleen occupies upon the blood stream. Or if not the same, they are closely analogous.

The writer has made many observations upon this supplementary action of the glandular systems, and hopes at a future time to report some of the clinical evidence which substantiates the view here given, as well as that showing the wider application of the therapeutic principles of the spleen. All of this evidence seems to point very directly to two important conclusions.

The first of these is that it is gradually being forced upon our understanding that nature, or nature's God, to go back a little farther, has provided the normal animal body with all of the elements necessary to defend it against the invasion of infectious disease. It is a well-known fact that some people appear to be naturally immune to all, or many infectious diseases. Others habitually have infectious diseases in a mild or trivial form, when those around them are having the same disease in a more or less virulent form.

The second conclusion is that we are now standing on the borderland of an undiscovered country in therapeutics, the exploration of which will unfold to us things quite as important as any that have astounded the medical world in modern times.

It is best to state at this point that splenic extract does not give equally brilliant results in all types of malarial infection; and here again it parallels in its action that of quinine. Its most brilliant effect is seen, as with quinine, in the acute tertian and quotidian types. Here it acts in the same specific manner, but it can be given at any time, without reference to chill or fever, and without any inconvenience to the patient. In the quartan and estivoautumnal types it more frequently requires the assistance of the hematinic; but even here its action is quite as prompt and reliable as that of quinine. Some recent observations of the writer have shown that the combination of lymphatic extract with the splenic extract greatly increases its beneficial effect in these more stubborn types of the disease, so that the results compare quite favorably with those in the tertian forms. Not only this, but the combination with lymphatic extract makes it possible to secure good results with a much smaller dose than when it is used alone. In the acute forms of all types, as might be expected, the most rapid results are seen, and the hematinic is seldom needed, unless the hemoglobin has been previously reduced by other causes.

A few typical cases will be selected from the great mass of the past six and a half years' work, and a few atypical or complicated cases. The microscope has not been relied upon entirely for diagnosis in these cases, although it has been used wherever the circumstances of the case made it necessary. The physician who attempts to rely wholly on the microscope for the diagnosis of malarial infections in general practice will find himself beset with many and grievous difficulties.

Case I.—Male, white, aged thirty-two, clerk. Has had fever continuously for two days, ushered in with a slight chill. Not feeling well for several days before; may have had some fever then, but does not know. No diarrhea; headache, aching of limbs, lassitude, slightly delirious. Temperature 105°, with slight morning remission. Diagnosis, estivoautumnal fever. Prescribed splenic extract, 5 gr. every two hours. Temperature fell steadily. At the end of the fifth day after the chill, the third after beginning the treatment, temperature was normal. No recurrence.

Case II.—Male, white, aged fifty, railroad engineer. Has been having a chill and fever every other day, with an exhausting diarrhea. Complains more of the diarrhea than of the chill and fever. Tongue

broad, flabby, frothy, pale, notched around the edges. No iliac tenderness. Prescribed splenic extract, 5 gr. every two hours the first day, and then three times a day. Diarrhea and chills stopped immediately. Rapid recovery.

Case III.—Male, white, aged twenty-five, barber. Gives a history of a severe chill two days before examination, followed by high fever. Sick all day and most of the night. Next day better. No chill, and went to work, but weak and not able to do much. On the day of examination had another hard chill, and temperature went to 105°. Diagnosis, tertian infection. Splenic extract, 5 gr. every two hours. Next day he went to work at his chair. There was no recurrence of chill or fever.

Case IV.—Male, white, aged forty-four, carpenter. Had severe sciatica of right leg. Not able to walk at all. Patient known to be susceptible to malarial infection. Diagnosed malarial origin. Gave splenic extract, 5 gr. every two hours. Third day he walked with a cane comfortably. Fourth day discarded the cane.

Case V.—Male, white, aged twenty-eight, barber. Had severe chill, followed by fever. Temperature now 104°. Was feeling fairly well until the night before. I did not wait for intermission, diagnosed malarial infection, probably tertian, and prescribed splenic extract, 5 gr. every four hours. The patient went to work at his chair next day and had no recurrence of chill or fever.

Case VI.—Male, white, aged forty-five. Chronic malarial poisoning. Microscope shows crescents and atypical forms of plasmodium, pigmented bodies, normoblasts, many lymphocytes; red cells show poikilocytosis. Blood plates few and scattered. No chills, but intense malaise and weakness. Prescribed splenic extract, 5 gr. every three hours, also extract of red bone marrow three times a day. Immediate improvement, rapid convalescence.

Case VII.—Male, white, aged twenty-eight, lawyer. Has been having quotidian chills, with continued fever, for several days. This morning did not get up. Aching of body and limbs. Temperature 104° when first seen. October 15 began to give splenic extract, 5 gr. every four hours. October 16 no chill; morning temperature 101°, evening temperature 103.4°. Increased dose of extract to 5 gr. every two hours. October 17 and 18 no improvement. Increased dose to 10 gr. every two hours. October 19 no improvement in fever; intense photophobia. Added extract of red bone marrow, tablespoonful three times a day. Temperature began to fall at once, but photophobia continued. Reduced splenic extract to 5 gr. every four hours, continuing the bone marrow. Photophobia ceased; temperature continued to fall until October 25, when it became normal.

Case VIII.—Female, white, aged thirty. Pregnant three months. October 14 and 15 had two chills each day. October 16, temperature 105°. Mucous membranes very pale, showing reduced hemoglobin. Double quotidian infection. Prescribed splenic extract, 5 gr. every four hours, and extract of red bone marrow, tablespoonful three times a day. No recurrence of chills.

Case IX.—Male, white, aged thirty, clergyman. Had a severe chill, followed by fever, aching of head, back, and extremities. Began with sore throat hoarseness, and a "cold," simulating influenza, but entire subsidence of fever the next morning betrayed the malarial infection. Did not wait for interval to pass, but gave splenic extract, 5 gr. every two hours. No recurrence of chill or fever.

Case X.—Male, white, aged sixty, farmer. Has had "fever 'n' agur" for two weeks. Sometimes two chills a day, but at least one every day. Has taken quinine, sarsaparilla, and several ague cures, without effect. Double quotidian infection, partially interrupted by the so-called "ague cures" the patient has taken. Gave splenic extract, 5 gr. every two hours the first day, and then four times a day. No more chills. Patient made a good recovery.

Case XI.—Male, white, aged five years. Has fever every night with nausea and vomiting. Fever subsides in the daytime, but has headache all the time. No chills, but seems to chill easily; shivers with the least change of temperature. Mild quotidian infection. Gave splenic extract, 3 gr. three times a day. Rapid recovery.

Case XII.—Male, white, aged thirty-five, coal miner. Has been feeling bad for several days. Today had a severe chill, during which he fainted before his wife could get him into bed; this was followed by high fever and delirium. Did not wait for interval to pass, but diagnosing malarial infection, prescribed splenic extract, 5 gr. every two hours the first day, and then four times a day. The man went to work in the mine the fourth day.

Case XIII.—Female, white, aged seventeen, schoolgirl. Had a chill and fever on two days with a day between on which no chill or fever occurred. Has aching of bones, back, and head, with coryza, and some cough. Tertian infection. Gave splenic extract, 5 gr. four times a day. The child went to school on the third day of treatment, but not feeling quite well. Added red bone marrow, teaspoonful three times a day. Symptoms disappeared.

Case XIV.—Male, white, aged seventy-three, clergyman. Continued fever with quartan exacerbation. Temperature runs from 101° to 103°, every fourth day going to 105°. Much pain and aching, especially in the back. Pulse weak and irregular. Urine heavily loaded with albumin. Diagnosis, quartan infection complicated with acute nephritis, or vice versa; difficult to say which is the primary disease. Gave splenic extract, 5 gr. every four hours, alternated with 5 gr. of gallic acid every four hours, and applied an osmotic poultice to the lumbar region. The gallic acid was stopped as soon as the albumin disappeared from the urine. In this case the gallic acid acted in a very happy manner, and it was not long until red bone marrow was substituted for it, the splenic extract being increased to 5 gr. every two hours. Recovery was slow but steady. It was fifteen days before the temperature ceased to rise in the evening, and show the quartan exacerbation.

Case XV.—Male, white, aged thirty, bookbinder. Has "winter cholera;" worse every other day. No distinct chill or fever; no iliac tenderness. Mild tertian infection, complicated with diarrhea. Gave splenic extract, 5 gr. every two hours. Next day reported himself much better. Bowels checking, and digestion improved, appetite returning. Uneventful recovery.

These fifteen cases give a fair idea of the rest. Many were typical, and many were not. Many were complicated with the widely varying conditions met with in general practice. It may be objected that cases should have been selected that were more typical, since so small a number was to be given. This may be true, but it was thought that a selection of general cases from every-day practice would give a better idea of the application of the remedy to all forms of infections than a list of perfectly typical cases.

It will be noted that in the cases cited the red bone marrow was given the preference as a hematinic. In the writer's article previously referred to the remark was made that theoretically a preparation of the red bone marrow would be the ideal hematinic to use with splenic extract, since it was the physiological remedy *par excellence* to supplement its action. At that time it had never been used in this connection, but subsequent experience showed that the opinion then expressed was well founded. Its effects begin very soon after its administration is commenced, and the splenic extract which before was powerless to do its work, immediately begins to act.

The thought may occur to some that possibly the red bone marrow would so revive the physical forces if it was pushed that it would enable the body to throw off the infection without the assistance of the splenic extract, but this is not so. The red bone marrow, as well as other hematinics, in themselves simply produce more and better food for the plasmodium; and its cyclical existence goes on with the same rhythm, although the resistance of the body is increased for the time being. The moment, however, the splenic extract is added, the miracle of physiological resistance, or cure of disease in the truest sense, appears.

In Case No. 7 it will be noted that photophobia was produced by a dose amounting to ten grains of splenic extract every two hours. This case is given for the purpose of calling attention to the fact that there may be a point beyond which the dose should not be carried. No efforts have been made to ascertain the toxic dose, if there be such. This can be done later by experiments on lower animals. For the present the therapeutic dose is all we need to discuss, and it is only necessary to note the physiological warning of the organism.

TUBERCULIN IN THE TREATMENT OF TUBERCULOSIS. WITH THE REPORT OF 167 CASES.

By G. R. POGUE, M.D.,

CANON CITY, COLORADO.

In presenting this series of cases for consideration as having been treated with tuberculin, it is understood that the drug was not used exclusively as a specific, but only as an adjuvant to other necessary therapeutic agents—fresh air, rest or graduated exercise, diet, hygiene, etc. It has not always been possible to carry out these latter measures satisfactorily, on account of the well-known difficulties of controlling the actions of patients in private practice. In sanatoria, where the patients are governed by the set rules of the institutions and are also under the direct supervision of the medical officers, such measures are much more effectively carried out, and the patient, therefore, has a better chance for the arrest of the disease, all things being equal. But since only such a small percentage of the vast army of tuberculous persons in this country can possibly be treated in sanatoria, we must make the best possible use of such other means as may be at our disposal, even though conditions are not always ideal, to combat the disease in such cases as may come to us for professional advice and treatment. Good results may be had if we give proper attention, not only to therapeutics, but also to the problem of educating the individual patient along proper lines. It is not sufficient that we simply inform our patients as to the proper course to follow, but we must educate them in the laws of prophylaxis, the value of fresh air, the dangers of overexertion or exercise, the proper diet, and the absolute necessity of following instructions laid down by their medical adviser.

The cases included in this report belong to a series treated between July 1, 1901, and January 1, 1905, covering a period of three and one-half years, with a lapse of one year and three months since the last cases were discharged, a sufficient time to observe results. The greater number of these cases have continued under observation for one or more years after discharge, some of them up to the present time. The report is based on the present condition of the patients as far as can be learned. Eight cases of Class I passed from under observation shortly after treatment, and, while they apparently, when last seen, should be placed with the arrested cases, the time for observation was too short to pass judgment, and therefore they are placed in the improved column. Those who received no permanent improvement are classed with those who died, in the "negative" column. The line of treatment followed has been fresh air, day and night, good nourishing diet, rest or exercise properly graduated, tonics and stimulants as required, together with tuberculin in small doses, repeated as often as necessary to suit the individual case. To the use of tuberculin is attributed the small percentage of relapses referred to below.

Of the 167 cases, 108 had been in Colorado for one to five or more years, taking the so-called climate cure, with no permanent results. They had all the advantages of climate and fresh air, and most of them the disadvantage of exercise when they required absolute rest. The most of them gave histories of apparent arrests followed by recurrences, acute attacks of pleurisy, and some of them long sieges of what was called pneumonia. None of them reported any permanent improvement similar to their improvement as is herein reported. One very noticeable trouble that they all complained of was "taking cold" on slight exposure, a trouble that very few have had to contend with since taking tuberculin.

The fifty-nine other cases were placed under treatment shortly after coming to Colorado, and about half of the negative results occurred among these fifty-nine. The 108 patients who had been in Colorado for a number of years previous to taking treatment did better, as a whole, than those who were put under treatment soon after arrival. Time had eliminated the "weaklings," or those who had a more virulent infection. They represented what might be called a better selected class of cases; but some few of these had been gradually losing ground. For instance, Case No. 118, Class II, came to Colorado in 1898 and after three years was allowed to return home; as usual, after three months' sojourn in the East, she relapsed and returned to Colorado, where she remained two years, with little or no improvement. Since 1904 she has been living in the East and enjoying perfect health.

Those patients who were put under treatment shortly after their arrival in Colorado and were really desirable cases did just as well as any other desirable class of cases. As the majority of them came here for the purpose of taking treatment, it was almost impossible to eliminate the undesirable cases, an unpleasant duty which the "admitting" physician has to perform for the sanatorium.

From the following table it will be seen that 64 per cent. of all cases treated had their disease arrested, and if we eliminate the sixteen advanced cases of Class III, we have 70.2 per cent. of arrests. Classified according to sex—103 males and 64 females—of the females, 32 were married and 8 have borne 11 living children since being discharged from treatment. In only one case was there any evidence of the disease following labor. Case 127, Class III, advanced, had, besides extensive pulmonary involvement, a severe tuberculosis of the larynx, was five months pregnant when first seen, and was put under treatment only at the earnest solicitation of her mother. Improvement was slight; she gave birth to a healthy male child about May 1, 1904, and died four weeks later. The child was immediately removed from all chance of infection from the mother and shows no signs of disease or inherited deficiencies. In the other seven women there was no evidence of recurrences. One woman has given birth to three, and one to two children since arrest of the disease.

The series will be considered as a whole, also in classes. The classification given below is that laid down by Durban of Davos.

Class I.—Disease of slight severity, affecting at most one lobe or two half lobes.

Class II.—Disease of slight severity, more extensive than Class I, but affecting at most two lobes; or severe and affecting at most one lobe.

Class III.—All cases of greater extent and severity than Class II.

Class	No. of Patients	Average Length of Treatment	Disease Arrested	Per cent.	Disease Improved	Per cent.	Negative or Dead	Per cent.
I.....	74	95 days	66	89.2	8	10.8	.....	....

Since the treatment of tuberculosis has for its object the arrest of the process, and that arrest is practically fibrous encapsulation, it is all-important that the arrest should be so perfect that under proper living and hygienic surroundings there would be little or no chance for a relapse of the disease. As to the time required after arrest of the disease before we can say our patient is "cured" there is no stated period; it depends upon many factors, such as the extent of the lesion, the organ or organs involved, the virulence of the invading bacilli, the recuperative powers of the patient, together with the mode of life and general surroundings of the individual patient. So far, we prefer to say that the disease is arrested, and if possible prevent a relapse. Whether some cases become reinfected after the lapse of years of apparent good health is an unsolved problem, but we do know that a great many of the so-called "climate-cured" cases relapse if they return to their homes in the East, while up to the present none of the cases herein reported, who are living or have lived in the East since taking tuberculin, have relapsed. To be sure, the number is not large enough to be of any great value in statistics, but several of them have visited in the East for three to six months without any ill effects, except the one case reported below. She returned to her former home and mode of life, disobeying all instructions as to exercise, fresh air, etc.

In the whole series of 167 cases, eleven patients relapsed, so far as is known at the present time (7.5 per cent.). Of these eleven, six improved again or later had an arrest of the disease. There were eight relapses in Class III, four patients died, two improved, and two are negative. In Class II there were two relapses, one took treatment for thirty days with evident improvement, when she stopped and resumed her former occupation as housewife (negative). The second later improved and is still living and in fair health, two years and three months after taking treatment.

In Class I there was only one relapse. This patient was under treatment only sixty days, when she returned East, where she remained for five months. The relapse was mild, and after three months' further treatment her disease was again arrested and has remained so—two years and seven months.

While the length of the treatment averaged ninety-nine days, the patients were kept under observation afterwards for from one to four and a half years, except the eight cases of Class I as mentioned above. The advantages of keeping arrested cases under observation for a considerable period after treatment are many. The most important advantage is to the patient, in that he can be advised and counseled at different times, and in this way prevented from depending on the false security, that he feels perfectly well and can again resume his old habits of life. By this after-supervision many cases can be guided back to perfect health who would, if left to themselves, very probably again break down. Often supervision also gives an opportunity to observe the results of treatment much better than can be done by correspondence or personal reports from the patients.

The diagnosis presented no difficulties in Classes II and III, except as for classification or ascertaining the extent of the lesions present. In Class I the tuberculin test was required in twenty-one cases to confirm the diagnosis, sometimes to convince the patient and sometimes to satisfy the examiner. The diagnosis was made in the other fifty-three cases of Class I by the ordinary method of examination and confirmed in forty-seven by the microscope.

I shall not attempt to consider all the complications met with. The most serious complication was tuberculosis of the larynx. There were nine cases in all, seven of which occurred in Class III; of these, five patients died and two are much improved. Two cases were seen in Class I (not primary), and in both cases the disease was arrested and 5 mg. of tuberculin given more than a year later gave no local or systemic reaction. There were eight cases of laryngeal paralysis from pressure on the recurrent laryngeal nerve; of these, two were negative, four were much improved, but are still hoarse, and two have complete restoration of voice.

There were three cases of purulent otitis media, one of five years' standing dried up after sixty

days' treatment, with fair return of hearing (1902) and the patient has had no recurrence since (December, 1905). One patient had complete loss of hearing, but no return of discharge, and one, Class III, had fair hearing, but has had occasional discharges of pus, but not nearly so troublesome as formerly.

Mixed infection was present in a great number of the cases, and when streptococcus infection was the chief factor good results were had from the use of antistreptococcus serum, as reported in *Colorado Medicine*, May, 1905.

There were nine cases with cervical adenitis present as a complication. All recovered, leaving little or no trace of the enlarged glands. One case in particular deserves special mention. Case No. 146, Class II, male, age thirty-four years, and weight 135 pounds. Family history negative. Has lived in Colorado most of the time for the last twenty years. First noticed enlargement of the cervical glands in 1897, since which time they grew gradually worse, had been discharging for over two years. Seen first, March, 1904. Glands, especially on the left, were broken down and discharging freely, with large open wound at upper border of clavicle. The upper lobe of the left lung involved. Sputum (washed) contained tubercle bacilli and streptococci; the pus from the suppurating glands contained streptococci; temperature, P.M., 38° to 39° C., chills and night sweats. Was given seven doses of antistreptococcus serum of 10 c.c. each, after which he was put on tuberculin, together with rest, fresh air, good diet, etc. In forty days he had gained twenty-three pounds, the ulcers were all healed, and cough and expectoration had ceased. Disease arrested and no signs of any recurrence since. On treatment three months.

That tuberculin was a failure, generally speaking, when first introduced by Koch, is a matter of medical history, and was due to several causes. It was then a crude product, its toxic, physiological, and therapeutic actions were unknown or not properly understood. It was administered to all classes of cases, with no regard to the extent of the lesions, temperature of the patient, or complicating infections. The idea had been given that it was a specific for tuberculosis, and it was expected to work wonders in regard to curing the disease. The dose was usually large and rapidly increased, and was repeated at short intervals, regardless of reactions or results produced. It is no wonder that it fell into disrepute, as no system could withstand such a continued course of poisoning, added to the already overburdened organism. The opinions held by many physicians to-day are those that were formed fifteen years ago. Disappointed with a drug that had promised so much to suffering humanity, they discarded it completely, and have paid little or no attention to it since except to condemn it whenever mentioned. Compare the doses and frequency of administration of the early investigators, or the doses recommended in the literature sent out with Koch's "T. R." (up to 10 and 20 mg.), with the doses advocated by Wright of London (0.001 to 0.004 mg.), and these small doses given only at long intervals and under the control of the "opsonic index." Whether Wright's opsonic index will prove successful in general practice remains to be seen. In the past, the only index we have had to guide us was the clinical, and those who are not supplied with the requisite laboratory facilities will be forced to depend on the clinical index in the future, as a guide to the dosage of tuberculin or other bacterial products.

My first experience with tuberculin was in September, 1900. It was given first 0.5 mg. every second day, and the dose increased 0.5 mg. at each dose until 3.5 mg. was reached, when it was evident that it was time to call a halt. As the experience was "personal," I am very familiar with the results. They were, to say the least, very unsatisfactory. After resuming the use of tuberculin in July, 1901, the dose was small—0.005 mg. to 0.1 mg., and in some few cases as high as 0.5 mg. have been given. It was never given when the patient's temperature went above 37.5° C. in the afternoon or evening. By keeping the dose down no systemic reaction was produced, and if a systemic reaction did occur from a given dose in a certain patient, the dose was always reduced to one-tenth or less of the previous dose, according to the severity of the reaction. In this way the patient was not exposed to what, to him, might prove to be a toxic dose, if repeated regularly.

The first step in the cure of tuberculosis that is recognized at present is that of encapsulation of the invading microorganisms. "If the tubercle is successfully isolated by fibrous encapsulation, there arises no consequence of moment to the organism, but if the attempt to wall it off be insufficient, the bacilli multiply rapidly, and some migrate radially into the surrounding tissues, spreading infection on every side." (Cornet.) If the capsule be sufficiently dense, there is less probability of its rupture during the stages of resolution. It must, therefore, be our aim to apply such therapeutic measures as will aid in thickening the fibrous capsule of the tubercle. It is a well-known physiological law that where there is a tendency to the formation of new tissue—the growing tubercle—an added blood supply or hyperemia aids greatly in its development. The action of tuberculin as observed in visible tubercles, is to cause a dilatation of the blood-vessels around the tubercle, thus bringing more blood to the seat of the disease. This hyperemia aids in the formation and thickening of the fibrous encapsulation. What rôle the hyperemia plays in the subsequent absorption or in the absorption of the tubercles already undergoing resolution, is a question as yet not fully explained. There is reason to believe that its action is similar to that described as "Bier's method" in the treatment of tuberculous joints and other localized infections by passive hyperemia. This local congestive action of tuberculin (active hyperemia) can be observed with the naked eye, in tubercles of the larynx, iris, mucous membrane, and skin, a few hours after a small dose of tuberculin. It is often noticeable that such tubercles disappear after a course of tuberculin, and a local reaction can no longer be produced even by diagnostic doses of the drug. In using tuberculin as a therapeutic agent, the object is to cause an intermittent—not a continuous—hyperemia around the tuberculous area, and at the same time not expose the patient to the dangers of excessive doses. From experience it has been learned that small doses produce hyperemia, while at the same time the tissues do not become immunized to the action of tuberculin. By this method we not only get encapsulation, but get absorption of small foci and single tubercles. Large doses have been seen to cause degeneration, if often repeated, of the new, susceptible granulating tissue, hence probably the cause of failure when large doses are used early in the course of treatment.

From a study of the histology of the tubercle it is evident that remedies directed at the destruction of the encapsulated bacilli must prove useless and disappointing. Antitoxic or bacteriolytic sera, no matter how potent, can be of no effect in the treatment of encapsulated tuberculosis. Such sera would be very valuable at such times as excessive toxins or bacilli were found free in the tissues, as the flooding of the lymph or blood stream by the rupture of a focus into the vessel, or in caseous pneumonia following the aspiration of a focus rupturing into a bronchus. Bacilli imprisoned in the tubercle are safe from the action of such sera, as the tubercle proper contains no blood vessels; besides, the internal pressure is greater than the external, thus preventing absorption of the serum into the tubercle. The myriads of tubercles in a given case, their different ages, and varied degrees of encapsulation, prevent all possibility of foretelling when an accident in the form of a rupture might occur, and if the focus were small, recognizing the condition until new areas are involved and show signs of disease. By that time it would probably be too late for the use of serum if we expected it to get its antitoxic or bacteriolytic action.

If such reasoning be at all correct, we cannot expect much from the serum treatment, even if we had one of the greatest potency, and the treatment of tuberculosis must depend either on thorough encapsulation of tuberculous foci, or the production of immunity, or on both. Wright's vaccination theory, and von Ruck's theory of producing immunity by the administration of increasing and often-repeated doses of "watery extract of tubercle bacilli," look feasible. Von Behring's new theory, which he does not even attempt to explain, appears to be on the line of production of immunity. How long an immunity will last is an unsolved question also. In both Wright's and von Ruck's cases recurrences took place, and it is fair to surmise that there was either insufficient immunity, or the immunity was not lasting. In the light of our present knowledge of the action of bacterial products, it would seem good practice to use tuberculin, for its local congestive action, in conjunction with the toxins used for production of immunity. Owing to the peculiar pathological changes produced in the tissues by the tubercle bacillus, tuberculosis will always be a slow disease to conquer, no matter what the line of treatment, and the line of therapy that gives the best and most lasting results should be followed without prejudice.

There has been no reference made to the authorities on the subject of tuberculin, as the literature of tuberculosis gives both sides of the question in full, but those who take the negative side seem often to have jumped at conclusions from the clinical results of a small number of cases, a review of which shows that the remedy was given in large and increasing doses, and their clinical material was generally of the "advanced class," already overburdened with the products of infection and retrograde tissue changes, and often complicated by associated infections. Tuberculin was given with the expectation that its specific action would result in the rapid destruction of the tubercle bacilli or a resolution of the tuberculous tissue, with little or no regard to the extent of the lesions. The work that has been done, during the last ten years, on the subject of bacterial products, by men whose standing in the profession must give weight to their statements, is very encouraging, and it would seem that the future treatment of tuberculosis must be by some of these bacterial products, plus the other necessary measures of fresh air, supervision, diet, etc.

The following cases are reported more fully on account of their special interest to the writer, and because none of the four patients was a favorable subject for treatment, they having exhausted all other sources then known to them.

Case 1, Class III, male, age thirty-nine years, weight 122 pounds. Family history negative. Had pneumonia (?) in February, 1899, hemoptysis in May, 1899. Came to Colorado August, 1899, weight 147 pounds. During the following twenty-two months had various quiescences and recurrences. By July 1, 1901, had large cavity formation in the upper lobe of the right lung, weight 122 pounds. Began the use of tuberculin July 8, 1901; improvement was slow but satisfactory, and at the end of six months, weight 135 pounds. The tuberculin treatment lasted over a period of two years (ten months in all). Present condition, disease arrested, no cough, no expectoration, and no tubercle bacilli in sputum for eighteen months; weight 157 pounds. During the course of treatment and since, he has continued to follow his occupation without any loss of time, except three days in February, 1904, when he contracted streptococcus infection, apparently in cavity in right lung, which infection rapidly yielded to the use of antistreptococcus serum, leaving apparently no bad results.

Case No. 16, Class I. Although a first-stage patient as far as the extent of the lesions were concerned, he seemed an unfavorable subject for treatment on account of his emaciated condition, family history, and years of exposure to infection. Male, age twenty-three years, weight 132 pounds. Seen first August 29, 1901, weight three years previous 156 pounds. He had been in Colorado for two years, but at none of the time showed any signs of improvement; on the contrary, he was losing ground. Father, mother, one brother, and two sisters had died of tuberculosis, during the last ten years prior to his coming West. He had morning cough, with expectoration, tubercle bacilli in sputum. Temperature P.M., 37.3° to 38.6° C., pulse, 90 to 110. Began tuberculin September 3, 1901, followed in short time by rapid improvement; in three and one-half months he had gained 30 pounds. During the treatment he did light work on a farm. January 1, 1906, weight 186 pounds, disease arrested.

Case No. 19, Class II, male, aged sixteen years, weight 81 pounds. Family history negative. Has had asthma for ten years, tried various climates and altitudes for three years before coming to Colorado in September, 1899, since which time improvement has been spasmodic. January, 1900, and March, 1901, had pneumonia (?), followed in each case by tardy recovery. Examination September 29, 1901, showed infiltration of upper lobe of left lung, tubercle bacilli in sputum, temperature 37.2° to 37.5° C., pulse 100 to 120. Under hygienic and dietetic treatment, with the addition of tuberculin, he gained rapidly, with increase in weight. He received tuberculin injections for six months out of the year. The disease was arrested, and since December, 1902, he has had no return of his asthma. Had croupous pneumonia of upper lobe of right lung November, 1903, crisis on the ninth day, convalescence complete and uneventful.

Case No. 154, Class II, male, age thirty-two years, weight 112 pounds. Came to Colorado

July, 1902. For one year he tried climate cure. No results; June, July, and August, 1903, he was given tuberculin in increasing doses, his physician claiming that if a little was good, more was better. The first two months his improvement was satisfactory, then the dose of tuberculin was increased to 5 mg., and later to 10 mg. every day, and the last week twice a day; at the same time he was ordered to take exercise. The results, as may well be imagined, were disastrous, rapid breaking down and severe hemoptysis. Seen first May 4, 1904. He began taking small doses of tuberculin, improvement was rapid and permanent up to the present. Weight, December 1, 1905, 137 pounds. Disease arrested. He has followed his trade as a barber since October 1, 1904.

From a study of the foregoing series of cases, the following conclusions have been drawn:

1. An early diagnosis is the most important step to the successful treatment of tuberculosis.

2. Tuberculosis may be arrested by proper treatment, with a fair certainty of a permanent cure.

3. Tuberculin is a valuable adjuvant in the treatment of tuberculosis, as evidenced by the recovery of twenty-eight out of thirty cases that were treated with practically nothing but tuberculin, while they continued to follow their ordinary occupations during the treatment.

4. Cases of tuberculosis treated with the addition of tuberculin show a much less tendency to recur than similar cases treated without tuberculin.

5. Tuberculin in small doses (0.01 to 0.5 mg.) seems to have a more curative action than when given in large and increasing doses.

6. No ill effects follow the administration of small doses of tuberculin.

7. Purely incipient cases improve very rapidly under the use of small doses of tuberculin, both as to the arrest of the disease and the clearing up of the diseased area.

8. Tuberculin should never be given to a patient who has fever or who is suffering from mixed infection.

9. Third stage cases, especially advanced cases, receive little or no benefit from the use of tuberculin.

PATHOLOGY, ETIOLOGY, AND TREATMENT OF PUERPERAL ECLAMPSIA, WITH A PLEA FOR THE KIDNEYS.*

By JOHN W. WINSTON, M.D.,

NORFOLK, VA.

Eclampsia is an acute morbid condition which may occur in the pregnant or puerperal woman, and is characterized by tonic and often clonic convulsions, of first the voluntary and later the involuntary muscles of the whole system, with more or less contraction of the arterial system, which is constant, with loss of consciousness ending in coma or sleep.

To consider any disease or decide upon its treatment, it is even more necessary to know its pathology than its specific cause; for often its specific cause, if there exists such, is the cause of the pathology, while the pathological lesions are the cause of the symptoms manifested in the disease, and the question arises in every disease whether it is more important to treat the disease or treat the pathology. In eclampsia the question arises as to what is the real disease, the pathological lesions or that which causes these lesions; thus it devolves upon us to seek out all the pathology and gather together all the suspected causes and study them in relation to each other and in relation to the symptoms manifested in the disease.

The time-honored theory that nephritis is at the bottom of this trouble must be considered, for it is so often present, and the close study of its functioning power and pathology give us a chance to know somewhat the condition of our patient, though, as Prutz says, "We cannot consider renal lesions as the anatomical substratum of eclampsia, for in many cases they would seem secondary," and as Bouffe de Saint Blaise says, "The kidney is often normal," or what is still more true, the kidney is generally normal until arterial contraction sets in, and even when pathological lesions are present in this organ its function is often not impaired, says Guénard.

I have seen kidneys throwing off hyalin and granular casts, and losing albumen, do their work well as long as the blood vessels in these organs were free from spasm. Edgar says that when the kidneys are diseased there is present an acute congestion; others say an acute nephritis or acute inflammation manifests itself, while others state that it is neither a congestion nor a true inflammation, but that the pathological lesion consists in a parenchymatous degeneration together with a slight inflammation and a tonic contraction of the local vessels, their state of tonicity depending upon the intensity of the cause. It must be admitted that in some cases inflammation has the upper hand, while in simple and true eclamptic cases the degeneration is the chief lesion. Because after death the vessels of the kidneys are congested, is no reason for saying that this was the condition when the disease was at its height. The cause of kidney impairment we must suppose bears some relation to the cause of the attack, for they are too often associated to leave any doubt that they are related. Many say that the kidneys become diseased, because of the elimination by them and the irritation caused in them by poisonous substances from the blood, either as the result of faulty maternal metabolism or toxic fetal metabolism. Against this theory is the fact that children of eclamptic mothers show in many cases similar degeneration to those found in the woman's kidneys, and it could hardly be supposed that a fetus excretes enough urine to do this damage. Some claim that the smaller vessels may be blocked by thrombotic formations caused by parenchymatous cells or giant cells supposed to be from the syncytium, or because of fibrin ferment set free by the placental cells. Massen has discovered an increase in leucomaines, and Kallman an increase in globulins, in the blood serum. Others believe that the general anemia which is very often present has something to do with a departure from the normal here, and still others that the local anemia caused by contraction of the blood-vessels in the kidney deprives the part of the already not overnutritious blood, and thus starves the tissues which become poisoned by self-waste and secreta. Certain it is that the maternal blood is not up to par, and there is no wonder that the kidneys are diseased, as they have to handle more material of an inferior character, poisoned by

*Read before the Norfolk Medical Society, March 13, 1906.

inferior maternal catabolism (leucomaines and globulins), fetal toxines, and at this perilous time have not only to contend with these substances but are robbed of proper nutrition also, often by general anemia, and cutting off of their own blood supply. In this connection it is not out of place to say, in proof of the above, that a parenchymatous kidney whose epithelium is necrosed because of improper blood supply will often do noble work if blood is furnished to it by vasodilation.

As early as 1892 Jürgens, Klebs, Pilliet, and Schmorl showed hemorrhagic lesions in the eclamptic liver in the region of the small vessels particularly, due to thrombotic formations, which were considered diagnostic of eclampsia. Williams has found pathological lesions in the maternal liver without exception in all his cases. The causes of these lesions resolve themselves into the same as those causing kidney trouble (bowel, skin, kidney, and lung disturbances), together with toxic materials thrown off by the placenta or fetus, contraction of local vessels with lowered nutrition resulting in self waste, and consequent increased permeability of vessels, with local exudation. Hematomata beneath the surface of the liver have been reported with rupture of capsule. The vitality of the part already lowered by lessened amount of inferior nutritive material supplied, would give sufficient ground for supposing that when the greatly increased pressure comes that in exactly such places as the liver diapedesis can easily take place, even without blocking by thrombi. Edema, thrombosis, hyperemia, and apoplexy of the brain can be explained as above. Degenerative changes in the heart have been found after prolonged chloroform anesthesia and are supposed to be due to this poison. Congestion and later edema of the lungs can be explained by heart failure, and especially by the fact that the pulmonary vessels possess less strength than vessels in most other organs, and with such high pressure present they give way to relaxation first, and the giant cells supposed to be from the syncytium block the track, and the blood under pressure behind then seeks the tissues. Owing to the constant contraction, which at some times is greater than at others in the blood-vessels, the vasavasorum are constricted, and in this way furnish a diminished amount of nutritive supply to their own walls, causing degeneration. This weakening of the vessels would cause them finally to give way to relaxation, which condition is often seen in the late stages of eclampsia. Constant contraction of the general arterial system, which is at some times greater than at others in eclamptic conditions, is in itself a pathological state if not condition. Some have found the suprarenal glands enlarged and claim that products caused by stimulation of these bodies cause the systemic contraction, but this is unlikely, as the attacks often occur before the uterus rises to contact with them.

Out of one hundred and thirty-three cases examined by Lange for thyroid enlargement, one hundred and eight showed the enlargement and none had eclampsia, and only one was nephritic; in the remaining twenty-two cases in which there was no enlargement, twenty had albuminuria, sixteen with casts, and six of these developed eclampsia. Lange removed one-fifth of the thyroid from ten pregnant cats; two died in coma twenty-three and twenty-eight days after the operation, and three had convulsions twenty-three and twenty-five days after the operation. No changes were noted in the other five cats, but on examination after they were killed similar changes in the organs of these were found. This lends weight to the fact that underaction of the thyroid is a cause. The pulse may present three pathological conditions; it may be of high tension, because of contraction alone, because of arteriosclerotic change, or it may be without tone owing to systemic and general arterial weakening.

Cause.—In considering the causes of this malady we must consider the cause of the pathology and the cause of the symptoms. The causes of the pathology have been spoken of above, therefore, we will now consider the etiology of the disease as a whole. The causes of this not too well understood disease are variously given by the many writers on the subject, amounting in number to about twenty-five different ones. "Like a bolt from a clear sky it sometimes comes," some have said; but in most cases that seem to appear in this way, with careful watching a cloud might have been seen gathering in the distance, such as a gradually increasing arterial pressure when the urea is not cut down and no trace of albumin has yet appeared. So many causes have been assigned that Zweifel has called it "a disease of theories." Twin pregnancy and hydramnios have been given the credit, but in over four thousand deliveries occurring at Columbia Hospital there were forty-eight cases of eclampsia, with only one twin pregnancy in the eclamptic cases and no report of hydramnios—thus eliminating not only these conditions but also the backing up of urine in the ureters supposed to be caused by these conditions. Primiparæ constitute 75 per cent., says Knapp, and a large percentage occur after the fifth month. Casts are more frequent in multiparæ than in primiparæ. Whether heredity has an influence has not been decided. Some have offered good reasons for bacterial origin, but on the whole this cannot stand, as examination of the blood shows a lack in the corpuscles and ready coagulation, but no bacteria. The whole is said to be the outcome of an autointoxication which is from protean decomposition, but no one has ever been able to demonstrate such in urine or blood. For a long time uremia was given the credit, but now it is thought often to indicate only the condition of the kidneys and the extent of arterial contraction. Uremia and eclampsia seem to me to be two entirely different conditions, though they may, as they often do, exist at the same time. Autointoxication was suggested by Bouchard and supposed to be proved by Tarnier and others because of diminished elimination of poisons through the urine at this time, as indicated by the urea passed, which intoxication gave rise to renal and hepatic complications, which complications accentuate the disease. These poisons by direct action on the kidney, etc., through elimination undoubtedly may do harm, but more harm is done by the stimulation of the oversensitive vasoconstrictor nerves, which causes a tonic contraction of the arterioles, being progressive and showing exacerbations. The truth of this statement is strengthened by the fact, often observed, that in a case that shows nephritis with granular and hyalin casts and a small amount of urea, the urea increases and the kidney improves if the vessels are kept relaxed. In a case so treated the kidneys eliminate much more poison and liquids, and at the same time improve; this fact seems to tell

us that the poison does not do the whole harm by local effect on the kidneys, but by some systemic effect.

To say that because hepatic lesions always occur, it is a hepatotoxemia (Bouffe de Saint Blaise), seems hardly fair, for there is some underlying cause which makes these lesions, and, after all, the underlying cause is the important one. Imperfect metabolic processes, such as those caused by constipation, hepatic disorder, etc., are well known to have a tendency towards causing an increase in nervous irritability and high arterial pressure. Thrombosis in the small vessels, caused by increased fibrin ferments from the placenta, syncytium cells, as stated above, some believe help to cause the lesions and thus the symptoms. Williams has found these giant cells away from the placenta in the small arteries in normal cases. Toxic fetal metabolism is supposed to be at the bottom in many cases, and this belief is strengthened by the fact that when the child dies (substances injected into a dead child in utero do not pass to the mother), the attacks often stop suddenly, and again by the fact that eclampsia occurs only in women with child. On the other hand, sudden stopping leans to the nervous theory, for the attacks often stop, even with the same amount of poison in the body, and the same pathology still existing. In the same woman some pregnancies are normal while others are eclamptic. Strumen reports a case in a woman eclamptic at her second and fourth pregnancy, while the others were normal. Such a case is on the side of the nervous theory. It is a well-known fact that country people are much less nervous than city folks, and it is also true that eclampsia occurs proportionately much oftener in the city than in the country. Attacks occurring in the mother after the delivery, and sometimes as late as a week afterward, and the fact that the child after the delivery very seldom has attacks, favor the idea that there is a nervous disturbance in the mother that is prerequisite. Serum and urine taken from an eclamptic mother after being sterilized have been proven by Schumacher to have little or no effect on animals when injected hypodermically. The great irritability of the involuntary muscles explains, in two ways, why expulsive pains in the uterus often come on with eclampsia—the uterus is made up of involuntary muscle and the arterial contraction causes an increase of carbon dioxide in the child, which is the most plausible cause of labor pains being initiated. Involuntary muscles, especially the uterine, become more irritable toward the end of pregnancy, and eclampsia is more frequent toward the end, furnishing another plea for the nervous theory which causes vasoconstriction.

Pathological lesions in the child are in many cases not observed, while in a few cases the child's kidneys and liver show the same lesions as found in the mother (Williams). This is in favor of a systemic poison, but as the kidneys in the fetus are very little active the elimination of poisons through them could scarcely account for the abnormal conditions here. This is a strong point in favor of the theory that in eclamptic cases the toxins (if of bacterial origin) or leucomains (if due to tissue metabolism) act, not by direct contact, but indirectly by their action on the vasoconstrictors and because the blood is deficient in nutritive material. The report of a number of cases of chronic nephritis, treated by means of a vasodilator (aconite) at the Roosevelt Hospital two years ago, was the first, so far as I know, to show that cases thus treated did well—while the aconite was kept up the urea increased and whenever stopped the urea would diminish, thus showing that the extent of arterial contraction can almost wholly control the output of urea through the kidneys. These steps, taken over two years ago, have not only revolutionized our treatment of interstitial nephritis, but have changed our ideas of this disease.

To-day, to pass a rigid physical examination, one's arterial system must be in good condition as well as his kidneys, showing that the physical condition of our little vessels is getting some of the credit it deserves. Underaction of the thyroid very probably exerts an influence in some cases, as explained above.

Sometimes there is only one attack at the end of pregnancy, which lends weight to the overcharged nervous explosion theory, and any manual dilation of the cervix tends to bring on another convulsion, and this dilation can in no way increase the poison nor add to the pathology, but acts simply by irritating the nerve center, which is already wellnigh uncontrollable.

Jaundice coming on suddenly after an attack means capillary contraction rather than acute poisoning. If eclamptic attacks are due directly to a systemic poison, why does the child live with the system in this condition, if the arteries are controlled? Williams says, and we all agree, that under proper treatment the subjective symptoms disappear, the urine and urea increase in quantity, and the kidneys improve, yet, just when we are congratulating ourselves, a convulsion occurs. Williams also mentions that a case was reported in which the urine was normal until the attack. These things seem to mean that there is a nervous discharge which commands high pressure in the arteries. Who has not noticed that these attacks follow dietetic imprudences, such as eating a lot of dates, and all know the harm at this time of excessive emotion and that if an attack has once occurred, the slightest shock, internal or external, may cause renewed paroxysms. Does not this mean nervous disturbance? Statistics show that two-thirds of the cases only have albumin, but at each attack there is an increase of albumin and decrease of urea, while after the attack the albumin diminishes rapidly and the urea rises fast, if arterial tension lessens. This is the condition, although even more poison is present in the circulation and passes the kidneys after an attack than before.

Increase in urea eliminated by the kidneys means the falling off in number of attacks, and it is also indicative of lessened arterial contraction. All the authorities admit that chloroform and morphine decrease the mortality, but who would say they do so by removing poisons from the system? These remedies must work by dilating the vessels and allaying nervous irritation. As the patient becomes worse and the coma deepens, then the pulse of course weakens, but the convulsions are also less severe.

Summing it all up, then, it seems reasonable to say that eclampsia, with its pathological conditions, is due to the presence of leucomains and globulins in the mother's blood, or if the parasitic theory be true, to toxins; to the formation of fetal toxic materials, both of which act slightly by direct action on the body parenchyma, but chiefly on the overcharged nervous system. If eclampsia is due to the presence of poisons in the body or to pathological kidneys, why do we not meet with it more often in such conditions as tuberculosis,

where the functioning powers of the tissues are already overtaxed? If the kidneys are to blame, why do we not find eclampsia oftener in multiparæ than in primiparæ? It is possible that in some cases eclampsia is a purely nervous disturbance without any anatomical substratum preceding the attack. It must also be remembered that the formation of poisons by disturbed body metabolism means necessarily some waste of the food supply. In 184 nephropexies done by Goelet of New York, the kidneys in many instances showing albumin and both granular and hyaline casts, the symptoms have entirely cleared up when the prolapsed organs were returned and fixed in their normal high position, showing conclusively that the kidney pathology was due almost entirely to a disturbance of the circulation. It is true that in such cases it is a passive congestion, while in eclampsia it is an active anemia, but in the end they amount to the same thing, for both act by diminishing nutrition, and kidney cells, as other cells, must consume themselves if they perform a function when the food supply is cut off. The convulsive symptoms of the attack cannot be explained by brain anemia, and it must be that the irritation caused in different ways amounts to a nervous explosion which causes an intense arterial contraction, this in turn causing brain and cord anemia which, for the time being at least, is a precaution on the part of nature.

Lobenstein and Welch, at the Lying-In Hospital, New York, report a neuroglioma of the right cerebral hemisphere during pregnancy, with symptoms of eclampsia. Rise of blood pressure takes place in the recumbent position. Over 3,500 feet above the sea level is what Oliver has shown is needed to raise the blood pressure considerably. The nearer our patients are to the sea level, the lower becomes the blood pressure. As a rule, over 160 m. of Hg. is necessary to produce symptoms.

Treatment, then, consists in prevention of the cause, treatment of the underlying causes when existing before the attack, treatment of the pathology, and treatment to meet the symptoms when they arise.

Prevention of the cause consists in keeping the pregnant woman in the best physical and mental condition possible, by looking after the input, output, rest and exercise, fresh air and sunshine. We should strive to remove any causes of indigestion and anorexia in any pregnant woman, for it is important that the woman at this time should have a full and liberal supply of nutritious food especially should she be able to digest and assimilate that all-important building material whose end product should be made to consist mostly of urea. The feeding of this nitrogenous food material should be given accordingly as its products are used and neutralized in the body. The kidneys may be doing their work by throwing off all the urea formed, but this is not enough, for the urea thrown off should be commensurate with the nitrogenous destruction in the system. The bowels should be made to do their work well, and the liver should be kept active, its secretion of bile free, for if these are not given the closest watch, products of decomposition will be absorbed, destruction and the necessary changes of the food in the liver will not occur. Diminution of bile in the intestines leaves the acid already present unneutralized, and allows the formation of others. The normal alkalinity of the blood in pregnancy should always be striven after, for this is the *sine qua non* in handling nitrogenous food, which food is greatly needed at this time. The skin must be active, and the kidneys should be kept washed with plenty of water, the reaction of which must be determined by the urinary reaction. Crofton says that kidneys which are inflamed should not be flushed even with water, as there is practically nothing to flush out, but with the arteries dilated we may dilute the castoff products. Moderate indulgence in fluids and care against overindulgence is the rule, as the arterial pressure is raised thereby and the mchanical burden of both heart and vessels is taxed. The amount of work to be done should be suited to the capacity, or, in other words, avoid hyperfunction. A mercurial purge, if needed, at intervals of ten days, removes the poison in the intestines, dilates the peripheral vessels, and increases the toxin-destroying power of the liver. It should be the rule to give a purgative and irrigate the colon in the pregnant woman, if the arterial pressure is rising, every time the patient complains of headache, dizziness, mental hebetude, dyspnea, etc. Dizziness is the first sign of disturbed cerebral arterial circulation. Increased oxidation and reduction necessary in the pregnant woman shows plainly that the lungs, too, must do their work well. if the best results are wished for. Rest of the body, which is a necessity, is no less important than rest to the mind and general nervous system; on the other hand, exercise is all-important, and while it of course should fall short of depressing, it should be taken much more than it often is. A cold bath in the morning, a walk after breakfast, a drive in the afternoon, and light dumbbells before retiring, regulated according to circumstances, are to be recommended. The habit some women have of staying indoors toward the end of pregnancy cannot be too strongly condemned, and the loose costume somewhat like a silk kimono now adopted as a fashionable style, is truly a Godsend. Fresh air and sunshine must always be sought. Violence of any kind is to be avoided, sudden cooling and other such imprudences must be guarded against.

The system at this time is prepared for increased work, and a departure from the normal in any way is more serious if not immediately repaired. The underlying cause, if a toxemia, from disturbed maternal metabolism or altered fetal metabolism, the poisons acting on an oversensitive nervous system, should be removed. The only way to remove these disturbances is to get the organs of the patient as nearly normal as possible, and in the meantime, while accomplishing this end, to counteract the effect of poisons as much as we can, especially by allaying nervous irritation with bromides, chloral, etc., and not let the irritation from these products keep the arterial tension up, by using the nitrites, aconite, veratrum, etc., as indicated. In the treatment of the pathological lesions, all we can do is to remove the causes as much as possible, and make the other organs (such as the skin) compensate and meet the effects of the poisons.

After marked symptoms arise the diet must, of course, be limited, but before this time it must always be remembered that the mother needs as much food as she can handle, the nitrogenous need increases more proportionately than the others, the input of which can only be regulated by a knowledge of the internal conditions. Gauge the intake by the output. The kidneys should not be imposed on at this time by being stimulated

to do more work, for if the system be made to supply the blood to the action of the kidneys, they will invariably do their work, even though badly crippled. Water taken at intervals and not too much at a time, to dilute, and a vasodilator to furnish the material, is all the kidneys ask. Alkalies enough to neutralize the abnormal acids are all that are needed, as an excess of them irritate the kidney, and any superadded irritation at this time should be especially avoided.

In proof of the fact that the kidneys will do their work if furnished the material to work on, even though diseased, I will cite the following case: Mrs. D. was sent into the hospital at 2 A.M., after having had two severe convulsions of eclamptic nature, brought on by bowel irritation caused by eating a lot of figs. Her pulse on admission was 96 and of quite high tension and bounding (this meaning plenty of blood with a *vis a tergo* and a *vis a fronte*). This patient's urea ran not quite one-half grain to the ounce of urine, which was scanty. She was given a vasodilator (veratrum viride ♏x) by hypodermic; almost immediately her pulse dropped to 55 and loosened considerably. Her arteries were kept relaxed, her bowels were moved well, and the skin made to sweat at every pore. At 9 A. M. the urea had gone up to two grains to the ounce of urine, the amount of which was considerably increased; at 2 P. M. the urea was five grains to the ounce of urine, and at 7 P. M. she was excreting 12 grains of urea to every ounce of urine, which was steadily increasing in amount. The urine throughout the day showed that the granular and hyaline casts were plentiful and had not lessened in number, thus proving that the much-improved excretory condition was not due to an improvement in the pathological lesions, but simply from a change in the blood supply to the kidneys.

The suggestion of splitting the kidney capsule, when these conditions start in midpregnancy, is, I think, an erroneous one, for it is not pressure of the capsule that does the harm. To tell when any disturbance begins to take place we must watch the working of every organ in the body. When the woman suffers dizziness, headache, and mental hebetude, the blood pressure should be carefully and systematically taken, not only with the finger, but with the sphygmomanometer. Diminished amount of urea is a sign in the infancy of disturbance, and simply states the amount of nitrogenous material that is destroyed and successfully neutralized in the body, if there is no circulatory disturbance in the kidney, but if the latter trouble is present it shows the condition of the connections at this safety valve as well. It should be borne in mind that while the pregnant woman throws off normally more urea than the non-pregnant, she also uses more building material, and the conditions are so variable that each woman is a law unto herself. Therefore urea estimation is not a safe guide to show what the system is doing, but other things being considered, it is a great help. The pulse is the first to give warning, and must always be carefully watched; it is the surest indicator of internal conditions that nature has. A steadily-increasing arterial tension must be combated by giving vasodilators and nerve sedatives, until the causes can be removed, for in itself it can do great damage. We do not have to wait for subjective symptoms to arise and note them to say whether the patient is improving, but the pulse and general observation will show us every time.

After convulsions arise we must first meet the conditions and then as well as possible remove the causes. In controlling the convulsions, chloroform, morphine, chloral, bromides, veratrum etc., are useful, and immediate delivery is often thought of, by vaginal or abdominal cesarean section, and dilating the cervix with rubber bags, steel dilators, or manual dilatation (Hay's method), followed by accouchement forcé. Whether or not immediate delivery is necessary should be decided by the condition of the patient when we first see her. A patient whose arterial tone is good and responds to treatment should be given a chance, for bringing on of the onset of labor is a dangerous thing, not only to the mother, but also to the child. Olshausen records a mortality of 25 per cent. in cases occurring after labor, in favor of the view that interference with labor is not necessary and, indeed, may be harmful in some cases. Of course if when we first see the mother the arteries have worn themselves out or she will not respond to treatment, then the only chance consists in immediate delivery, with blood-letting, injection of salt solution, and stimulation. Venesection is only transient, and while it is the quickest way to reduce the blood pressure, in prolonged cases it is not by any means the safest.

If the convulsions are controlled by sedatives and vasodilators, and drowsiness, unconsciousness, and coma disappear after the attacks, the expectant plan can be followed, but if the pulse gives way to the extent of depression, and convulsions recur, even though less severe, and coma deepens, there is no time to lose, and delivery must be accomplished. In cases where vascular paralysis, due to the arteries being tired and worn out, is present, of course to use vasodilators with such a condition is criminal, but blood-letting, followed by infusions of salt solution, with stimulation and immediate removal of the child (vaginal cesarean, if possible), is in urgent need. In cases where acute nephritis exists, some are inclined to say that chlorides should not be used in the infusions, as they take fluids off into the tissues, but chlorides are active in helping to remove the fatigue stuffs and stimulate the individual tissue cells, which is more important than a little edema. When high arterial tension is present, it is well to give fluids cautiously or according to their elimination, at no time allowing the irritable vessels to become over-full or even full. Crofton aptly says that there is as much sense in trying to cure typhoid fever by amputating the rose spots as to cure a systemic disease (modern Bright's) by attention to the kidneys. Williams says that after convulsions have once occurred, then the woman must be delivered, but it seems more reasonable to decide what is best to do by the response to treatment and the present condition. Veit and Charpentier advocate morphine until the cervix is dilated, and then forceps. Zweifel says that convulsions cease in 66 per cent. after delivery, and that 28.5 per cent. die as result of expectant treatment. In a list of 4,000 cases of labor at Columbia Hospital, Washington, D. C., there were 48 eclamptic cases, with 12 maternal deaths, giving a mortality of 25 per cent., and all these cases were treated in an expectant manner, chiefly by vasodilators (veratrum) and sedatives (chloroform, morphine, chloral, etc.).

This expectant treatment is 3 per cent. ahead of Zweifel (who advocates immediate delivery), and most of these cases were not seen until the convulsions started or a short while before. In a

patient seen from the beginning of the attacks, who persistently grows worse and in whom all we can do does not restore normal arterial tension, then after one convulsion, or even before a convulsion, we should think of delivery. In all cases we are almost safe in acting according to the condition of the patient and the readiness with which she responds to treatment. I have seen patients who responded to treatment do well after two convulsions, carry the child to full term, and be delivered in good condition. After delivery is decided upon, vaginal cesarean section seems best indicated if we want quick work and the child is small, but on account of a bad-looking cervix and the urinary fistula that results in many cases from this procedure, if time will allow, rubber bags combined with Harris' dilatation and forceps are better. When the cervix is cartilaginous, abdominal cesarean section is sometimes advised, as Hillman gives 0.5 per cent. mortality from this operation. Hygienic treatment, the results of which are closely studied by the effect on arterial tension, will in a number of cases give the careful observer due notice of coming trouble, and although Blumreich has shown eclampsia to be of nervous origin in animals, the nerves cannot act without the arteries giving signs. Thyroid extract and milk diet have made edema, albumin, and other signs disappear. This, coupled with the fact that underaction of the thyroid is a most suspicious cause, justifies us in always observing this organ. Sweating, which in many instances is excellent treatment, if persisted in for too long a time, may become a harmful influence. Hot packs, now so much used, certainly allay nervous irritation a good deal, they dilate the blood vessels of the skin and help elimination, but if continued for too long time they pass the depressant stage and become very exhausting.

THE GALVANIC AND OTHER TREATMENT OF THE PROSTATE.

By JOHN V. SHOEMAKER, M.D., LL.D.,

PHILADELPHIA.

In revising for publication my late clinical lecture on prostatitis, I here present it anew with the mention, then omitted, of my employing the galvanic current which has been my mainstay for several years in the treatment of that affection. I do not by this statement imply any more than I say, that, in my treatment, constitutional means are not also employed, and that laxative medicines, diluent drinks, buchu, belladona, opium suppositories, and hot baths are not effective; but merely wish to say that, above all other means that I have found for reduction of hypertrophy of the gland, the galvanic current stands, in my estimation, first.

Its employment has also a remarkable incidental advantage. In all persons the flow of electricity in the rectum from the negative pole increases the caliber of the rectum, as though it had been inflated, and causes a simultaneous downpour of mucus. In some persons, additionally, these effects from the galvanic stimulus are followed immediately by urgency for defecation, which, of course, affords great relief from pressure on the congested and tender gland. In both instances, therefore, the congested areas are sensibly relieved. The administration is of the simplest character. All that the patient has to do is to make sure that it is to the *negative* pole of his battery that he attaches the reophore belonging to the metallic bulb of the prostatic electrolyzer before inserting it in the rectum. Should he, through carelessness, attach the reophore of the positive pole to the bulb to be inserted in the rectum, he would, by the hardening of the prostate, receive an injurious instead of a beneficial effect from the flow of the electrical current.

The prostatic electrolyzer, with a small wet-battery, has given instantaneous and immense relief to many sufferers. If my readers could only see some of the letters that have been received from patients, expressing a grateful sense of relief from gnawing or shooting pains, if they could have seen the reductions of hypertrophied glands, from the administration of the current, that I have witnessed, they would be entirely satisfied of the efficacy of the treatment.

I wish it to be particularly noted that I have here recommended a wet-battery. The manufacturers of the prostatic electrolyzer took a notion not long since

to sell it with a box of dry-cells instead of wet-cells. Thereupon I wholly withheld my recommendation to patients to purchase the prostatic electrolyzer unless they could procure with them wet-batteries. I am perfectly well aware that if a man gets a box containing enough dry-cells he may, for a time, have a battery adequate for the small amount of electric current needed for treatment of the prostate, which amount, however, let me say in passing, although never great, varies with the idiosyncrasy of the individual and the condition of the prostate. But, after all, what has a man really in the way of efficiency in owning a box with a number of dry-cells in it? A mere receptacle for holding the cells. The patient does not know to what degree they may have run down. Of course wet-cells also run down in the course of use, but, with a box of wet-cells and a bottle of exciting fluid, the patient can keep his bat-

tery always at the same strength of current. For the purpose of prostatic treatment a battery of dry-cells is like having a box of torpedoes. Set them off, and one has only the box left. Having a battery of wet-cells and a bottle of exciting fluid is like having a gun and powder; one can indefinitely load and fire the gun with the same force as at first. A wet-battery capable of producing thirty volts affords a margin for the range between the least sensitive and the most sensitive prostate. The Keystone Electric Company of Philadelphia, as a consequence of my remonstrance, has discarded the dry-battery and now supplies the electrolyzer with wet-cell batteries. A cut of the electrolyzer is presented on page 178.

Hypertrophy of the prostate does not usually appear until after forty years of age. In some instances, however, superinduced by masturbation or by excessive venery, it has occurred as early as thirty, and with all the usual senile characteristics. The morbid condition is not so much hypertrophy of the muscular stroma as of enlargement of the whole gland in the form of chronic inflammation. Usually, when there is only enlargement of the third lobe, the affection is glandular in character. In hypertrophy of the lateral lobes, with the formation of a bar, the morbid condition is nearly always fibromatous. There may be present in the tissue of the gland small fibromatous tumors, or they may be glandular and fibromyomatous. In most cases of prostatic hypertrophy there is also involvement of the deep urethra. Especially is this the case when there has been indulgence in masturbation or in excessive venery. Introduction of instruments by unskilled hands is a source of aggravated evil.

In the progress of the disease, the mucous membrane becomes much swollen and edematous; in consequence of which difficulty is experienced in micturition, tending, on account of retention and decomposition of urine, to produce the complication of cystitis. If hypertrophic changes occur chiefly in the lateral lobes, the firmness of the triangular ligament prevents enlargement at the apex. Hence comes about bulk towards the vesical orifice, which, being pushed upward and forward into the bladder, forms a large pouch posteriorly and a small one anteriorly. The posterior pouch becomes a reservoir for residual urine; and since the muscular wall of the bladder in this area is weaker than that of the other portion of the bladder, every time the viscus contracts in its function of emptying the bladder the pouch is stretched more and more, and thus, besides obstructing the urinary flow, becoming larger, receives and retains more and more residual urine. The mucous membrane over the trigonum becomes affected, and this still further obstructs the flow of urine. Should the hyperplastic process develop mainly towards the rectum, defecation is hindered and chronic constipation ensues. With the formation of a bar at the neck of the bladder, due to hypertrophy of the mucous membrane at the apex of the trigonum, between the lateral lobes, accompanied with the development of small tumors around the vesical orifice, a great obstruction is presented to micturition.

The normal structure of the bladder-wall may become much changed from the onset of prostatitis. Owing to distention and irritation from the residual urine, its muscular layer may become thin, inelastic, and atrophic, and produce an enormously enlarged viscus. On the contrary, the mucous membrane and the muscular fibers may become hypertrophied, so that the viscus may be able to hold only a few fluid-ounces. Often vesical calculi form and lie in the pouch described posteriorly to the orifice, but these may not give rise to symptoms of uneasiness. Should small tumors be present, they may become encysted by the condensed phosphatic salts present in the residual urine.

The symptoms of prostatic hypertrophy are seldom, if ever, confined to the prostate gland alone. The functions of the parts adjacent are also impaired by hypertrophic changes. With most patients, frequent micturition, especially at night and in the early morning, is the first symptoms noted by them. The recumbent position causes congestion in both bladder and prostate. As the disease progresses, however, more frequently repeated urgency to micturition takes place. Among the first symptoms is also that of increasing difficulty of micturition and an accompanying dribbling of urine. Seldom, at first, does the sufferer regard these symptoms as of much moment, ascribing them to natural changes arriving with advance of age. But soon, from increasing congestion in it and in the prostatic urethra, the bladder becomes perceptibly irritable even to his observation. Micturition becomes intolerably frequent and painful, with gradual decrease in the velocity and in the volume of the stream passed. A large amount of residual urine supervenes, accompanied by pyuria and decomposition of the urine.

The symptoms that usually next arise are either mild or severe pain radiating along the urethra and reaching the glans penis. This pain is aroused at the beginning of micturition, leaving a scalding or burning sensation when the operation is finished. On suddenly-cold, or on damp, chilly days, this pain is intensified. In some cases enlargement is uniform throughout the gland, but not sufficient to manifest itself to the patient until he happens to catch cold or to neglect to empty his bladder at proper intervals of time. Then it may be so congested as to prevent him from producing a drop. This complete retention of urine may, indeed, be the very first symptom to call the attention of the sufferer to his ill condition. Acute prostatitis varies in individuals; and even, at different times, in the same individual. There are sufferers with prostatitis who become apprehensive long before this stage of the affection is reached. In some patients there is a dull, aching pain in the scrotum, testicles, or rectum. A more rare symptom is incontinence of urine. The complications that may arise are hemorrhoids, prolapse of the rectum, inflammation of the testicles, tunica vaginalis, and epididymis. Should there be much cystitis, and of long standing, the sufferer experiences urinary poisoning and his general health is much impaired. He is liable to have headache, nervousness, insomnia, general malaise. He is usually constipated, with tongue heavily coated and with breath of urinous odor.

The diagnosis of hypertrophied prostate is easily made from its symptoms, and from digital examination, per rectum, of both gland and bladder. Instrumental examination of the prostatic urethra and of the bladder is obtained with bougies, coudé catheters, and stone-crushers. Thus can the caliber of the prostatic urethra and the condition of the bladder-wall be ascertained. The last information is acquired by passing the instrument gently over the bladder-walls. Then we readily detect, through tactile sensibility, whether or not the surface is rough, smooth, or tuberculated. Soft bougies should be employed to detect stricture of the urethra, which is often a complication of the disease.

Case I.—Mr. A. M., aged seventy-one years, mar-

ried. Occupation, lawyer. For a year before consultation with me he had had a slight dribbling toward the end of micturition. He next noticed that the stream was becoming smaller, and was projected with less force than normal; and then that it gradually became decidedly feeble and halting. At night he was obliged to get up two or three times to urinate. During the day micturition became more and more frequent. Upon digital examination I found that the prostate was enlarged in all directions, and was quite painful to the touch. The urine was negative and free from pus.

Case II.—Mr. J. B. S., aged fifty-six years, married. Occupation, superintendent of ironworks. He had had, up to the time he consulted me, a history of perfect health, except for the two previous days. Two days before he had taken cold, and on the following morning was unable to urinate. His family physician had catheterized him twice during the second day. When I digitally examined him I found the prostate so enlarged that I could not sweep my finger over the whole area of the gland, the attempt giving him exquisite pain. He was able to void his urine soon after treatment began.

Case III.—Mr. H. G. F., aged forty-nine years, married. Occupation, clerk. When eighteen years of age he had had gonorrhea, but, following three weeks' treatment, had been apparently cured. He recognized that he had always been excessive in venery. A year and a half before he called upon me he had noticed that in urinating the stream was becoming smaller and smaller in volume. Finally the flow had become difficult to start. Two months before he saw me he had begun to feel a burning sensation along the urethra after micturition, and he had been obliged to rise two or three times every night to empty his bladder of its irritating contents. In the daytime micturition was also more frequent than it usually is. Digital examination revealed enlargement of the third lobe, the urine was alkaline and, microscopically, showed the presence of pus and of broken-down blood cells.

Case IV.—Mr. W. K., aged sixty-four years, married. Retired merchant. Five months ago he was first obliged to rise once during the night to relieve his bladder. Soon he was obliged to rise for the same purpose twice during the night, especially toward morning. His next symptom was slight tenesmus after micturition. Later, urgency to urinate increased in frequency during the day. When he first called upon me he was obliged to urinate every hour. His urine had an ammoniacal odor, was alkaline, looked cloudy, and contained pus and broken-down red and white corpuscles. Digital and instrumental examination revealed a vesical bar and hypertrophy of the lateral lobes of the prostate.

Case V.—Mr. J. H. B., aged fifty-one years, married. Occupation, traveling salesman. At first he had noticed a slight pain in the glans penis before and after micturition. Soon after that he became unable to sleep all night without voiding his urine, pain, and urgency to make water increasing, especially at night; the urgency becoming still greater, pain correspondingly increased, radiating into the left testicle and the rectum, producing desire for defecation. On damp, cold, rainy days, if neglecting to wear overshoes, or in otherwise feeling or catching cold, the disease was aggravated. Examination for stone was negative. Digital examination revealed a large, painful prostate. Examination with bougies proved that he had a stricture. His urine was alkaline, and contained pus and broken-down red and white blood cells and albumin, perhaps derived from the blood. The insertion of bougies produced a severe attack of catheter fever.

Case VI.—Mr. H. A. D., aged fifty-two years. Had been a sufferer for the past fifteen or sixteen years from severe gout. He had had many attacks of it, involving both feet and hands. His secretions were all characteristically gouty, especially his urine. His bladder had become irritable, and he had been obliged to rise several times a night to urinate. The irritation had finally become so great that he had been obliged to rise from ten to twelve times during the night. During the day he had been obliged to leave his duties every now and then to empty his bladder. The gouty characteristic of the urine was immediately corrected by me, but the irritability of the bladder remained for a while. On digital examination I found the prostate much hypertrophied, especially as to the middle lobe. Galvanic treatment was employed morning and evening, with the prostatic electrolyzer, for from ten to twenty minutes at a time. The patient took the dosage of from ten to twenty milliampères in strength. The prostate, at the end of three months, exhibited a more contracted and a softer constitution of body than at first. The excruciating pain that had been experienced before treatment began had long since disappeared. In the daytime the patient could easily retain his urine from three to four hours, and was obliged to rise only once or twice during the night. His bowels had been constipated before the treatment began. This was incidentally corrected by the use of the prostatic electrolyzer. The patient now regards himself cured of his ailment.

This last may justly be regarded as quite a severe case, and it shows how amenable to treatment prostatitis is, if only this be instituted within a reasonable time.

It may be thought that I am prejudiced against dry cells under all circumstances. They have their uses. What I object to is the employment of dry cells for the purpose of electrolyzation, because patients generally have no means of ascertaining the value, if any, of the electromotive force that they are using. And, lest the present reader should doubt my ability to judge of such a matter, I append a few lines of opinion from the Edison Manufacturing Company, which quotes from Cooper's book, "Primary Batteries," as follows:

"Speaking of dry cells, Cooper says: 'Certain defects are frequently observed. Deterioration takes place if the cells are kept in stock, even if no current is taken from them, and is shown chiefly by loss of electromotive force and increase of internal resistance. Another defect is that known as bursting. This bursting generally takes place in cells which are on circuit, but it is also liable to occur in cells which have never been used. A dry cell has the disadvantage that, when it is exhausted, it is of no further use, and must be thrown away.' "

So much for what the Edison company quotes. But it begins its own statement by speaking of the disadvantage which people have who do not possess volt meters, ammeters, or other instruments for testing electromotive force. The average user of the prostatic electrolyzer is not so equipped. With a dry-cell battery he is at the mercy of his ignorance of what his battery is doing for him. That is the single point at which I am driving. I wish, in prescribing batteries to go with the prostatic electrolyzer, to have them such (wet batteries) that the dosage, which I have also prescribed, shall be secured to the patient; not something less, or, perhaps, virtually nothing.

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, August 4, 1906.

APPENDICITIS AND MUCOUS COLITIS.

THE increased attention which has been accorded to appendicitis as a surgical disease, to be treated by operative measures at the earliest possible opportunity, has, no doubt, resulted in the performance of an operation in many instances in which the subsequent course of events showed that such a radical method of treatment was not indicated. This haste to operate is favored by an experience which has shown that the uncertainties connected with an acute attack of this disease make surgical interference the procedure of choice; but the haste which is often manifested also stands in the way of an accurate and careful diagnosis, and when a closely simulating condition is the cause of the patient's symptoms the removal of the appendix naturally fails to accomplish the desired end. One of these conditions is mucous colitis. This was discussed in a recent address by Prof. Dieulafoy, who showed that it was a disease likely to be confused with typical appendicitis. The patients have usually had one or more attacks of colitis, they are constipated, they may have from time to time evacuations of slimy, bloody stools, and complain of pain in the region of the cecum or the ascending, transverse, or descending colon. As appendicitis is often traced to a previous enterocolitis, the other clinical features of the case may be overlooked or underestimated, and the diagnosis of appendicitis given to the patient and operation advised. When the latter is done no evidence of peritonitis is to be found, there are no adhesions, and the appendix is entirely normal, as is proved by later histological examination. Furthermore, the attacks to which the patient has been subjected come on again after the operation, and the other symptoms of the colitis continue as before.

Dieulafoy is not inclined to attribute to the histological diagnosis of appendicitis the usual amount of faith with which this is ordinarily received. It has been found that in many cases when the gross appearance of the appendix was apparently normal the microscope showed bands of fibrous tissue, hypertrophy of some of the crypts, and a hemorrhagic follicilitis. Dieulafoy claims that if the appendix of an adult be examined after death, no matter what the cause of the latter, such changes will always be found, particularly in the distal portion of the organ, and they are of no especial importance. The effusions of blood and the follicular hemorrhages are not, it seems, evidences of appendical inflammation, but are due to trauma produced during the operation.

Such diagnostic errors will not occur if greater weight is given to the clinical picture of appendicitis as a whole rather than to any one symptom. The presence of pain in the right iliac fossa does not necessarily point to appendicitis, particularly if it is associated with an enterocolitis. Dieulafoy does not believe that appendicitis is one of the results of an enterocolitis, and it has been his experience that the presence of pain in the right iliac fossa in such cases points rather to a typhlitis than an appendicitis. The term typhlitis has not found much favor on this side of the water heretofore, but there are evidences that the necessity of the distinction is being recognized. Appendicitis, particularly that variety which is likely to be confused with an attack of colitis, affords a well-marked, characteristic clinical picture. The patient is suddenly seized with the pain, and there are no prodromal symptoms, whereas the individual suffering from colitis will give a history of intestinal disturbances extending over months and years. In both conditions there is tenderness in the right iliac fossa, but in the latter it is never so closely identified with McBurney's point; moreover the muscular rigidity, the hyperesthesia of the skin, nausea, vomiting, and a rise of temperature associated wtih true appendicitis are absent in mucous colitis.

There is no doubt that the feverish haste to operate in every suspected case of appendicitis is gradually abating and greater efforts are made to establish the diagnosis firmly before subjecting the patient to a procedure with which there must always be associated an element of risk. Dieulafoy's warning as regards the confusion of appendicitis with certain forms of colitis is in line with the conservative views regarding appendicitis which are being more universally adopted. This constitutes, however, in no way a restriction to the axiom that when we have to deal with an actual case of this disease early operation is the best possible procedure for the welfare of the patient.

PREMATURE ANNOUNCEMENTS OF MEDICAL DISCOVERIES.

IT used to be urged as a reproach to scientific medicine that it surrounded itself with mystery and refused to take the public into its confidence, working along behind closed doors and jealously guarding its secrets from the laity. And pity 'tis that in these latter days such a reproach can no longer be made. Now the consumption cures and the cancer cures are published to the world in the lay press before they are definitely formulated in the minds of their discoverers, and long before they have been put to the test of actual experience. It is impossible to calculate the misery of disillusion that followed the false hopes created by the premature publication of the tuberculin discovery. The wretched failures of the early experiments with this substance not only dashed the hopes of thousands of the tuberculous, but threw discredit upon scientific medicine, and brought a really valuable remedy into such disrepute that it was years before its subordinate but definite position as a therapeutic measure was established. We hope that the recent publication of an alleged cure for cancer will not have an equally sad and deplorable outcome.

In *McClure's Magazine* for August is an enthusiastic account of the value of trypsin injections in the treatment of this disease. The author, Dr. C. W. Saleeby, describes the researches made by Beard of Edinburgh which led him to the employment of this remedy, and on the strength of two inconclusive experiments on mice and two incomplete trials of trypsin injections in man, proclaims that at last a definite cancer cure has been found. "The giving of the widest and most immediate publicity to these facts," he says in conclusion, "seems to be a proceeding from which it would be cruel and cowardly to refrain." And what are the facts which it would be cruel and cowardly longer to keep from a suffering world? Two cases are reported, in neither of which an absolute disappearance of the tumor has occurred, and in one of which it is acknowledged that the patient is yet in danger of his life, "by reason of the poisonous action of the disintegration products of the growth;" and two cases of Jensen mouse tumor are related, in neither of which had the tumor disappeared when one animal died and the other was killed, but was only in process of "degeneration." A report such as this might be published in a professional journal, with an apology from the author for the paucity of his cases, without great harm, for it would stimulate to a trial of the remedy by others, and so lead to the collection of sufficient data upon which to base an intelligent opinion of the value of the treatment. The medical reader, knowing the uncertainties of diagnosis, and familiar with the erratic course of malignant growths, would accept the report with reserve and await the results of further experimentation before abandoning the knife and committing his patients to the peril of an untried, or at least unproved, remedy. But the layman who had been told that a cancerous tumor had been seen to melt away under the influence of trypsin injections would naturally believe that an absolutely certain remedy had been discovered, and would refuse the knife in his own case, possibly and probably with fatal result.

It may be that in trypsin a true remedy for malignant disease has been discovered, and the cases of Beard and of Shaw-Mackenzie, as related in the latter's work on cancer,* raise the hope that this may be true; but these cases are by no means conclusive, and merely offer encouragement for further trials. When, as Gaylord said in his paper read before the Medical Society of the County of Kings, reported in another column of this journal, a spontaneous cure of cancer in mice took place in 22 per cent. of his laboratory cases, it is unpardonable to announce to the world that trypsin is a certain cure for the disease, because in two mice which had received the injections the tumors were found in a condition of regression, even when this evidence is strengthened by two unconvincing cases in man. Even in the happy event of the discovery of an actual cure for cancer, the premature announcement of the fact in a lay magazine, before the remedy has become familiar to the profession and the proper method of its application has been established, must be deplored. At the best it exposes the remedy to the fate of tuberculin, and at the worst it raises false hopes in the minds of many sufferers from operable cancer which will lead them to reject the surgical measures which are as yet the only ones which the conscientious physician can advise.

*The Nature and Treatment of Cancer, by John A. Shaw-Mackenzie, M.D.; New York: Wm. Wood & Co.

CIGARETTE SMOKING IN GREAT BRITAIN.

THE MEDICAL RECORD has on several occasions commented editorially on the subject of cigarette smoking; in fact, the question has obtruded itself so frequently in press discussions, and has been made the subject of so much debate in the various State legislatures, that no self-respecting medical journal could do otherwise than refer to the matter with more or less frequency. In all these discussions by the press and the legislative debates the assertion is made with the utmost confidence that every kind of cigarette is harmful in the highest degree, and that perhaps the majority of lunatics in the country become so on account of their addition to the cigarette habit. Most sensational tales of the evil results of this form of smoking were playfully bandied about, and the general public was taught to believe, and many persons did believe, that cigarette smoking is quite the quickest road to perdition, and is responsible for the ruin, body and soul, of countless individuals. In this vigorous crusade against the cigarette some States have even gone so far as to invoke the aid of legislation to stay the progress of the cigarette habit, and a strong prejudice has been created against cigarette smoking under any conditions.

Both the MEDICAL RECORD and the London *Lancet* took up the question some few years ago and decided that cigarette smoking *per se* was no more harmful than other forms of smoking; in fact, investigations went to show that cigarette smoking under certain conditions is the least noxious form of tobacco indulgence. These conditions are that the tobacco and paper used in the manufacture of cigarettes must be pure, that smoking must not be indulged in until adult age, and that the smoke of cigarettes must not be inhaled. When these conditions are fulfilled the cigar and pipe are more hurtful than the cigarette. Of course it cannot be denied that young boys, and even children, do smoke cigarettes, that the tobacco used in their manufacture is not always of the best quality, that cigarette smokers do frequently inhale the smoke, and that the convenience of the little paper roll tempts to overindulgence. It is the abuse of cigarette smoking and not its use that works evil.

The above homily is suggested by reading of the wave of indignation which has recently swept over Great Britain with regard to the matter. An American, the cause of this spasm of virtue on the part of the British public, was assisted by the ever-ready yellow press. Mr. Gaston, the American in question, is reported to have said: "You ought to prohibit the sale of cigarettes imported from America. The American cigarette is the worst thing our country sends you—worse than Chicago tinned meat." He furthermore went on to say: "Cheap cigarettes are drugged. Cigarettes are noxious articles, because of the cheap quality of the tobacco used, the filthy conditions under which they are produced, and the drugs used." This indictment is a sweeping

one, and only to a slight degree justified by the facts of the case. Moreover, it must be borne in mind that cheap cigarettes are by no means peculiar to America; indeed, cigarettes are sold at a cheaper rate in Great Britain—manufactured, too, in that country—than in the United States. When it is understood that cigarettes are retailed in shops of all kinds, in every part of London at least, at the price of a packet of six for one penny (two cents), it will be obvious to all that America has not a monopoly of cheap cigarettes. In truth, the patronage of children and young boys is especially catered to by certain tobacco manufacturers in England; perhaps to a greater extent than in any portion of America. As regards the purity or otherwise of cheap cigarettes in Great Britain, although we do not recollect to have seen an authorized analysis of the same, it would seem reasonable to assume, from the price at which they are sold, that inferior qualities of tobacco are used in their manufacture.

Undoubtedly cigarette smoking by the young is an evil, and one that should be scotched as soon as possible. Discreet legislation should aid in preventing cigarette smoking by children and youths. Also the point that both tobacco and paper are pure should be absolutely insisted upon. Parents, too, in the case of the young, might use their influence to good effect. Of course it would be well if no one smoked at all until he had arrived at the age of twenty-one, or even more; but to pass a law with such a provision would be interfering too greatly with the liberty of the individual.

It is probable that legislation with regard to cigarette smoking will be introduced into England ere long, as it is evident, from all the signs, that a strenuous crusade is to be undertaken there against the paper-wrapped cylinder.

The Diagnosis of Joint Affections.

Although the diagnosis of joint affections has been much facilitated by the application of radiography to this use, the interpretation of the negatives obtained is not always easy. The close apposition of the various structures concerned, and their lack of contrast in density, make the problem of securing ideal depictions of joint conditions one of the most exacting that the radiographer is called upon to solve, and innovations intended to diminish its intricacies are to be viewed with interest. A suggestion that seems promising is that made some time ago by Werndorff and Robinson of distending the synovial cavity of the joint with oxygen before taking the radiograph in order to secure better differentation of the soft parts. The idea has been taken up with enthusiasm by Wollenberg (*Medizinische Klinik*, No. 20, 1906), who has devised an apparatus for the generation of oxygen by the catalysis of hydrogen peroxide with potassium permanganate; and Hofia (*Berliner klinische Wochenschrift*, No. 28, 1906), presents a series of twelve radiographs, showing what may be accomplished in this way in obtaining radiographs of the knee joint. The synovial pouches of the normal joint are strikingly demonstrated, and it needs but a little study of the pictures, showing dislocated cartilages, floating bodies, rheumatic and other forms of arthritis, proliferations of the synovial fringes, tuberculous disease of bone and synovia, etc., to convince one of the clearness with which intra- and periarticular changes are revealed by using this technique. The injections are said to be painless, or nearly so, and the absorption tion of the injected oxygen usually takes place in from twenty-four to forty-eight hours. It ought not to be very difficult, by allowing oxygen to flow from one of the commercial tanks into the smaller reducing chamber provided with an improvised manometer, to obtain the gas under the pressure of one-half to three-quarters of an atmosphere, which is said to be most suitable for the purpose, without resorting to the somewhat cumbersome and expensive apparatus of Wollenberg. Apparently there is no danger connected with the maneuver. Aside from the diagnostic uses of the method, it is not inconceivable that under some conditions it might prove of therapeutic value also.

The Serum Treatment of Cancer.

Much has been said in the papers recently of a publication by Dr. Bashford of the British cancer fund laboratory regarding the serum treatment of cancer in mice. He is quoted to the effect that "We are now able to produce at will all the features of spontaneous cancer in mice, and to protect healthy mice from all consequences of inoculation with experimental cancer. This having been achieved, it is not too much to hope that further development of the experimental study of cancer will ultimately yield results having a direct bearing on the nature and treatment of the disease." This is apparently no more than was announced by Dr. Gaylord of the Buffalo laboratory a year or so ago, but it is significant coming from the British cancer fund commission, which has until now regarded the subject of the cause and prevention of malignant diseases with absolute agnosticism.

News of the Week.

The "Pacific Medical Journal."—The first issue of this journal since the San Francisco disaster appears as a double number for May and June. It is devoted entirely to the medical aspects of that catastrophe, and is full of matter of absorbing interest. The entire plant of the *Journal* was destroyed by the fire, and with it went Dr. Winslow Anderson's large medical library, all the files of the *Journal*, and many manuscripts. The nucleus of a new library has been supplied by a number of the medical publishing houses, and the genius of the editor has revived his always interesting journal. Friends who have back numbers of the *Pacific Medical Journal* are asked to send them to Dr. Anderson, 1914 Pacific avenue, San Francisco, in order that the files may be reconstructed so far as possible.

Board of Health Exhibition.—On July 30 the Board of Health began its series of open-air stereopticon exhibitions intended to educate the masses in matters of hygiene and to discourage the use of patent medicines. The chief efforts at present are being directed against tuberculosis, and the views shown are photographs of sanatoria, diagrams of healthy and diseased lungs, etc., and a series of slides, each giving some hygienic direction tersely expressed, such as warnings against spitting in public places or using patent medicines, and directions as to the manner in which the consumptive poor can increase their chances of cure. These directions are written in both English and Yiddish,

and later on it is the intention to add other languages. Other exhibitions will be given at intervals of a few days in the various small parks of the lower East and West sides, the last one being scheduled for October 1.

Foreign Regulations Concerning Meat Importation.—The health officers of London have formulated regulations regarding the importation of canned goods, which provide that the name and address of the manufacturer and the date of canning be impressed on all tins; that 1 per cent. of each consignment shall be opened on importation and examined before the goods are marketed, and that food intended for canning shall be inspected by an independent official prior to being canned. The use of preservatives is strictly prohibited. The Bundesrath of Germany has voted to prohibit the importation of pickled meats unless lymphatic glands are present to make trustworthy examination of the meat possible.

Food Adulteration in Germany.—According to a consular report received by the Bureau of Manufactures, food adulteration has been carried to an extreme degree in Germany, and it is stated that trained chemists are regularly employed by large and supposedly reputable firms for the purpose of performing the sophistications scientifically. The report states that there were in Germany in 1888 1,400 prosecutions for adulterating food products; in 1898 the number had increased to 3,000; in 1901 to 3,586, and in 1903 to 6,000. Butter, sausage, wines, chocolate, cocoa, brandy, and medicines have been found to contain absolutely dangerous substances used for adulteration.

Enforcing the Free Alcohol Act.—A new department of the Bureau of Internal Revenue has been established for the purpose of carrying out the provisions of the denatured alcohol act passed a short time ago, and Dr. A. L. Crampton of Maryland has been made chief of the division. The regulations governing the administration of this law will not be completed until the return to this country of Internal Revenue Commissioner Yerkes, who is in Europe making an inquiry into the operations of denatured alcohol laws in England, Germany, and Holland.

Infant Mortality in Chicago.—Twenty years ago, out of every thousand infants in Chicago, under one year of age, 220 died annually. Last year, 1905, only 5,831 infants died out of 42,005 living under one year of age, a proportion of less than 139 in every thousand, and a decrease of considerably more than one-third (37 per cent.). Twenty years ago, of the total yearly deaths of infants in this city, one-third occurred in July and August, and the average of the July and August deaths of infants for the last decade was nearly one-fourth (24 per cent.) of the yearly total. Last year, out of the total 5,831 infant deaths, 1,317 occurred in July and August, a proportion of 22.5 per cent. of the total, and a decrease of nearly one-third (32.4 per cent.) in the midsummer mortality of infants, from the rate of twenty years ago.

Infant Mortality from Diarrheal Diseases.—The mortality statistics of this city show that, while between May 28 and July 22, 1905, there were 2,070 deaths from intestinal disorders among children less than five years of age, this year only 1,475 children succumbed during the same period.

Operation on Prof. v. Eiselsberg.—It is reported that Prof. v. Eiselsberg of the University of Vienna, who has advocated early operation in appendicitis rather more warmly than most European surgeons, was himself operated on for this condition on July 27. It is stated that he said nothing of his illness to his assistants until, after having performed two appendectomies himself, he ordered the room prepared for a third operation and announced himself as the patient.

An Appendicitis Epidemic.—Three members of a household in Flushing have recently suffered from appendicitis, and it is stated that in June, in the Flushing Hospital alone, twenty-nine operations for appendicitis were performed, while there were many such operations at the homes of the patients.

Dr. Frank Billings of Chicago is reported in the papers to have presented to the Marshall Field estate a bill of $25,000 for one week's attendance during the late millionaire's fatal illness in this city. If this report is correct, Dr. Billings probably holds the record for big charges by an internist—$25,000 for seven days, or $3,571.43 a day, at the rate of $1,300,000 a year.

Disapproval of Newspaper Notoriety.—At a meeting held June 14, the Montgomery County Medical Society, of Illinois, adopted a resolution censuring physicians who allowed reports of their cases to appear in the daily press.

Roosevelt Hospital.—Improvements to cost $12,000 are being projected for this hospital, and the plans have been filed with the Building Department. It is intended to enlarge the hospital by making over the present two-story amphitheatre at the south end of the administration building on Fifty-ninth street into a four-story building. Double floors are to be introduced in the additional stories, and a large lecture hall will be built on the new second story. The two new upper floors will be fitted as dormitories for the hospital employees. A new amphitheatre will be erected on another part of the hospital grounds to replace the abandoned one.

Immigration Statistics.—The revised figures of the Bureau of Immigration show that during the fiscal year ending June 30 the number of immigrants admitted to this country was 1,100,073, as against 1,026,499 for the previous twelve months, a gain of 73,574. It is stated that most of the newcomers were from Austria-Hungary, Russia, and Italy, and that they were somewhat inferior in type to those of previous years. During the year 12,433 applicants for admission to the ports of the United States were debarred, for various causes, principally disease of some sort. Seventeen aliens were arrested and deported, on the ground that they had been brought to America for immoral purposes. Thirteen criminal proceedings were instituted against those who were responsible for the importation of these people, and ten of the defendants were convicted.

Death at Advanced Age.—The death is reported from Laporte, Ind., of the oldest woman in the State, and possibly in the country, who died on July 30, at the age of one hundred and twelve years. She was born in Volgravitz, Poland, and came to this country in 1870. One of her claims to distinction was that she had seen Napoleon on the occasion of his invasion of Russia in 1812.

A Day Without Accident.—On July 30 twelve hours passed without a single death being reported at the Coroner's office, the time running from 10 o'clock Sunday night to the same hour on the following morning. It is stated that this is the first time that such an interval has occurred in many years.

The Meat Question in Germany.—According to the official statistics 43,421 horses and 2,151 dogs

were slaughtered in Germany for food under Government inspection during the first three months of 1906. This was an increase of 7,522 horses and 366 dogs over the number slaughtered during the same time in 1905. It is estimated that among the poorer classes the consumption of this sort of meat was much larger than the official records show.

The New Jersey State Board of Medical Examiners.—At the annual meeting of this board, held in Trenton on July 5, the following officers were elected: *President,* Dr. W. H. Shipp, Bordentown; *Treasurer,* Dr. C. A. Groves, East Orange; *Secretary,* Dr. John W. Bennett, Long Branch.

Organization of the Medical Society of the Southwest.—An association, having this title, was organized on July 16 at Kansas City, Mo., subject to ratification at the initial meeting, to be held at Oklahoma City in the latter part of October. Delegates from the State societies of Missouri, Kansas, Oklahoma, Indian Territory, Arkansas, and Texas effected the organization and elected the following as officers of the new body: *President,* Dr. Frank Lutz of St. Louis; *Vice-Presidents,* Drs. J. T. Wilson of Sherman, Tex., Marion King of Texarkana, Ark., P. S. Mitchell of Iola, Kan., and C. S. Bobo of Norman, O. T.; *Secretary and Treasurer,* Dr. F. H. Clark of El Reno, O. T.

Medical Society of the Missouri Valley.—The nineteenth annual meeting of this society will be held at Council Bluffs, Ia., on Thursday and Friday, September 6 and 7. Special railroad rates will be in effect at this time within a radius of one hundred miles of Council Bluffs. Papers must be in the hands of the secretary, Dr. Chas. Wood Fassett of St. Joseph, Mo., before August 10, in order to secure a place.

Central Iowa Homeopathic Medical Association.—At the meeting of this society, held in Cedar Rapids on July 19, these officers were elected: *President,* Dr. Chas. H. Cogswell, Jr., Cedar Rapids; *Vice-President,* Dr. A. E. Crew, Marion; *Secretary,* Dr. H. C. Parsons, Anamosa; *Treasurer,* Dr. Struble, West Liberty.

Quarterly Journal of Inebriety.—The summer number of this publication has been considerably enlarged and improved in typography, and the table of contents includes several contributions of more than ordinary interest. The front cover contains an excellent portrait of the late Dr. N. S. Davis.

Minnesota State Tuberculosis Sanatorium.—The first building of the Minnesota State Tuberculosis Sanatorium, which is to be located at Walker, will be erected at once at a projected cost of about $59,000, including the construction of outdoor sleeping shacks.

Obituary Notes.—Dr. G. J. CAMPBELL of Halifax, N. S., son of Dr. D. A. Campbell, died on July 19 of pneumonia, at the age of twenty-six years. Dr. Campbell was graduated from Dalhousie Medical School two years ago, and, after taking a post-graduate course at Johns Hopkins University, had begun practice at Halifax. He was married on July 10, and his illness began on his wedding trip.

Dr. E. M. MCQUESTEN of Nashua, N. H., died suddenly of heart failure at Squirrel Island, Me., on July 19, at the age of sixty-two years.

Dr. GEORGE W. JONES of Colfax, Ia., died on July 14, at the age of fifty years as the result of a fall in getting into his carriage.

Dr. THOMAS JEFFERSON EATON of Kansas City, Mo., died on July 18, at the age of sixty-six years. He was born in Circleville, O., and after serving as hospital steward in the Civil War, he was graduated from the Ann Arbor Medical School in the class of 1867. He practised in Dalton, Ind., Baldwin, Kan., and in 1871 he settled permanently in Kansas City. He was well known as a chemist and toxicologist, and was a member of the first faculty of Kansas City Medical College.

Dr. ROBERT R. LIVINGSTON of Plattsmouth, Neb., died on July 20 in Lincoln, Neb., at the age of forty years. He was graduated from the Omaha Medical College.

Dr. A. A. MCWHORTER of Burkeville, Tex., died on July 15, at the age of eighty-one years. He was born in Alabama, and began the practice of medicine in 1849.

Dr. WILLIAM P. BRANDEGEE of this city died on July 30 of apoplexy, at the age of forty-two years. He was a native of Brooklyn, and after being graduated from Yale University received his medical degree from the College of Physicians and Surgeons in 1889. He was visiting surgeon to the New York Eye and Ear Infirmary.

Dr. ALEXANDER HUTCHINS of Brooklyn died on July 30 in his seventy-first year. He was born in this city and was graduated from Williams College in 1857. He received his professional education at Harvard Medical School and the New York Medical College, from which he received his degree in 1860. During the Civil War he served as assistant surgeon in the navy and later began practice in Brooklyn. He was for three terms president of the Medical Society of Kings County, and was also President of the Medical Society of the State of New York, in 1883. Dr. Hutchins was for twenty-five years a visiting physician at the Brooklyn Hospital, and was also consulting physician at St. Mary's and St. John's hospitals.

Correspondence.

QUININE IN CHOLERA.

To the Editor of the Medical Record:

SIR:—Referring to the letter in the MEDICAL RECORD of February 17, 1906, page 269, of Erskine B. Fullerton, M.D., of Columbus, O., with regard to the treatment of cholera with quinine, in which he invites particular attention to the results obtained by Dr. Ussher, at Van, Asiatic Turkey, and cites his experience as fully verifying his prediction that the mortality from cholera should fall somewhere between two and twenty-five per cent., it will no doubt interest Dr. Fullerton, as well as your readers, to learn the results obtained in the following cases which were consecutively treated at the San Lazaro Cholera Hospital, by the quinine method which he advocates:

CASE I.—J. A., aged 24; male; Filipino. Admitted 6.35 P.M., May 10, 1906. Constant vomiting made administration of quinine impossible until 11.30 P.M., when ten grains of quinine sulphate were given by the mouth; vomited before one hour had passed. 1.30 A.M., high enema of five hundred c.c. of a 1-1,000 quinine sulphate solution was given and retained. Several attempts made afterward to administer quinine by the mouth, but the drug was always promptly vomited. 5.30 A.M., 500 c.c. of a 1-1,000 quinine sulphate enema given. At 8.15 A.M., 10 grains of quinine sulphate given per mouth and retained about one hour. 10.15 A.M., high enema consisting of 500 c.c. of a 1-1000 quinine solution given and retained. At noon, 10 grains of quinine were given by mouth. Patient comatose. Died at 3.10 P.M.

CASE II.—J. S.; aged 36; male; Filipino. Admitted 9.30 P.M., May 13, 1906. 9.45 P.M., 2 capsules of five grains each quinine sulphate, given per mouth; same vomited about 10.15 P.M. 10.30 P.M., high enema consisting of 500 c.c. of a 1-1000 quinine solution given and retained. 11.30 P.M., 10 grains quinine given per mouth. 12.30 P.M., 10 grains quinine given per mouth. Patient comatose. Died 1.30 A.M., May 14, 1906.

CASE III.—C. M.; aged 18; female; Filipina. Admitted 4.20 P.M., May 15, 1906. Ten grains quinine given per mouth at once; promptly vomited. Five grains quinine solution given hypodermically 5.30 P.M. High enema con-

sisting of 500 c.c. of a 1-1000 quinine solution. Died 6.05 P.M., May 15, 1906.

CASE IV.—A. M.; aged 19; female; Filipina. Admitted 12.10 P.M., May 23, 1906. 12.30 P.M., ten grains quinine sulphate given by mouth; vomited ten minutes later. 12.50 P.M., high enema consisting of 500 c.c. of a 1-1000 quinine solution. 1.30 A.M., 10 grains quinine given by mouth; vomited 2 P.M. 2.30 P.M., 10 grains of quinine given per mouth, and retained. 3.30 A.M., 10 grains quinine given per mouth and retained. 4.30 A.M., 10 grains quinine given per mouth and retained. 5.30 A.M., patient in comatose condition. Died 7.20 A.M.

CASE V.—S. C., aged 26 (?); male; Russian. Admitted 8.30 P.M., June 2, 1906, in fairly good condition. 8.45 P.M., 10 grains quinine given per mouth; promptly vomited. 9 P.M., high enema consisting of 500 c.c. of a 1-1000 quinine solution, given and retained. 11 P.M., 10 grains quinine given per mouth; promptly vomited. June 3, 1 A.M., 10 grains quinine given per mouth and promptly vomited. The same dose was repeated at 3, 5, 8 and 9 A.M., with similar results. 12 o'clock noon, high enema, consisting of 500 c.c. of a 1-1000 solution of quinine. 10.45 P.M., 10 grains quinine given per mouth; impossible to retain. Patient continued to vomit everything which was given during the remainder of June 4 and 5. Morning of June 6 was able to retain small amount of food. Ten grains quinine given per mouth every hour until five doses had been taken. Same treatment repeated June 7. Morning of June 8, two doses, 10 grains each, of quinine, given. Patient died 8 P.M. June 8.

From the foregoing cases it will be seen that for the five cases, treated in the order in which they arrived at the hospital, the mortality was one hundred per cent. In addition to the quinine given in capsules, pills, and solution, stimulation with strychnine, hypodermically, was used, artificial heat was applied, and saline enemas were given as indicated. In the last case reported, it will be seen that the patient remained in the hospital from June 2 until June 8, and that during a considerable portion of this time he was able to retain the quinine, but without effect.

In this connection it will probably be interesting to record that in the treatment of cholera in the Philippine Islands it has been the experience of physicians who have treated many cases, often several hundred, that during the active stage of the disease the vomiting is so continuous that it is impossible to administer quinine, and that patients who pass successfully through the vomiting stage usually recover without further treatment. During the vomiting stage, the use of physiological saline solutions by transfusion, and the maintenance of the body temperature by the application of artificial heat to the extremities, etc., offer a better chance for success than any other form of treatment that has been tried.

VICTOR G. HEISER, M. D.

P. A. SURGEON, U. S. P. H. and M. H. SERVICE, DIRECTOR OF HEALTH for the PHILIPPINE ISLANDS; CHIEF QUARANTINE OFFICER for the PHILIPPINE ISLANDS.

MANILA, June 20, 1906.

INFANT FEEDING.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—There is an error in your report of my remarks on Dr. H. L. Coit's paper read before the Medical Society of New Jersey, in that I am made to express an opinion which is exactly contrary to my beliefs. The main points of my remarks were that a baby's digestive organs cannot always digest the same amount of the same kind of food in the same number of minutes. Therefore, I do not believe in exact regularity of feeding. The old-fashioned way of feeding the baby a little every time it cries is about as bad as anything could be. Scientific regularity of feeding is a great improvement on this, but I think there is room for further improvement. Do not feed the baby until its stomach is absolutely empty and it is really hungry, whether the interval be three hours or eight hours. Then feed it until its stomach is full and distended. Do not feed again until there has been ample time for digestion, evacuation, contraction, and rest. It is feeding too frequently that dilates the infant's stomach, not feeding too much at one time.

D. E. ENGLISH, M.D.

MILBURN, N. J.

The Immortality of Dogs.—Prof. Howison, head of the department of philosophy at the University of California, has asserted his belief in the immortality of dogs and some other of the lower animals, on the ground of their intelligence, as evidenced by their power to reflect and to overcome hindrances to their intellectual faculties.

OUR LONDON LETTER.

(From Our Special Correspondent.)

NEWCASTLE ROYAL HOSPITAL—TWO HEALTH CONGRESSES—DILATED VEINS IN CHILDREN—BULLET IN BRAIN—INSPECTION OF SCHOOL CHILDRFN—FOOD QUESTION—ROYAL COLLEGE OF SURGEONS ELECTION—TROPICAL SCHOOL—OBITUARY.

LONDON, July 13, 1906.

ON Wednesday the King and Queen went to Newcastle and opened the Armstrong College and the new Royal Victoria Infirmary. Of the latter the King, then Prince of Wales, laid the foundation stone on June 20, 1900, on behalf of Queen Victoria. This new hospital has cost £300,000, the late Mr. John Hall giving one-third of this sum and Lord and Lady Armstrong another third. The building is on the pavilion system and provides 450 beds—200 more than were available in the old infirmary. The ward pavilions are two-storied, the ground floor being intended for surgical cases, and the operating theaters being also here. The upper floor is for medical cases. The administrative block is the center. The site is described as the best possible, and the buildings as a whole are a credit to the great city of Newcastle-on-Tyne, the chief magistrate of which the King has directed to have the title of Lord Mayor in commemoration of their majesties' visit. A statue of Queen Victoria in front of the hospital was also unveiled by the King.

The twenty-third annual meeting of the Royal Sanitary Institute was opened on Monday at Bristol, and the proceedings will close to-morrow. The Lord Mayor opened an exhibition in connection with the congress, the High Sheriff gave a reception, and Bristol gave entertainments on the usual liberal scale. There were conferences of municipal representatives, of medical officers of health, of engineers and surveyors to sanitary authorities, veterinary inspectors, sanitary inspectors, and so on.

Sir Edward Fry in his presidential address defined science as the exact knowledge of subjects which admitted exact knowledge, and said our increase of scientific knowledge had seriously added to our duties as individuals and citizens. In former years, on the appearance of scarlet fever or smallpox, the head of the family called in a doctor, possibly a nurse, and kept the bedroom door shut. His drains he let alone, unless some horrible odors called upon him to throw down a few bucketfuls of water, having done which he felt he had done the whole duty of man. Now all this is changed, nurse and patient are secluded, and disinfection reigns. The medical officer of health has to be notified, drains are looked into, and every new drain-doctor finds his predecessor was wrong, his system faulty, and now only perfection in sight. Even then the householder may doubt whether he or the bacilli will win the day. As is the fate of the individual, so, declared the president, is that of the municipality or other group of citizens responsible. The State requires due provision for public health, at any rate a proper state of drains, and here the local authority finds itself in a dilemma. If it uses the nearest stream, it is obnoxious to the attacks of riparian proprietors; if it puts its refuse on land adjoining, tenants and landlords object to the nuisance. From conflicts thus brought about a mass of litigation has accumulated, and the labors of an army of experts contending for opposite opinions have not yet presented us with an exact sanitary science.

After an interesting review of the periods of advance and retrogression from the time of the ordinances of Mena to our own age, Sir Edward Fry dated our serious work on sanitation to the earlier reign of Queen Victoria. In 1847 several acts were passed, containing codes or collections of provisions as to cemeteries, gas works, and town improvements. The next year, 1848, the first general public health act was passed, constituting a central controlling authority, the Board of Health, and providing for the creation of local Boards of Health. In the early seventies so great interest had grown up in sanitation that the brilliant leader of the Conservative party in 1871 propounded as the watchword for his followers the maxim: "Sanitas sanitatum et omnia sanitas." The act of 1872 divided all England and Wales into sanitary districts, urban and rural, with a local body in each to secure the due administration of the laws regarding public health. In 1875 a further act gathered into one the whole body of legislation on the subject, and so formed an important epoch in our sanitary history. In the next year this Institute was founded, it had done much, and he trusted the labors on which they were now entering would be very fruitful.

Another Health Congress was opened on the 27th ult., viz., the Royal Institute of Public Health. This was at Cork, and Dr. Windle presided. In his address he pointed out the great need of Ireland in respect to sanitation. The people were decimated by tuberculosis, which had been steadily increasing, while in England and Scotland it was just as steadily diminishing, as shown in the death rates. In 1864 it was 3.3 in England and 2.4 in Ireland, and slowly

the two lines converged, until in 1881 they met at 2.6. Then they began to diverge again, Ireland taking the worse direction, reaching 2.9 in 1904, while England was 1.7. With this advancing rate from tuberculosis there was also an increase of lunacy. Of every 10,000 persons in Ireland, 52.6 are registered as lunatics or idiots. There is also an increase of this rate in England and Wales, the figures being 34.71, nearly 11½ less than in Ireland.

The cause of these scourges in a country so favorably situated for health had puzzled many. Some attributed the calamity to alcohol, but though the people drank more than was good for them, his knowledge of both countries led him to conclude that in the country parts they were less given to this vice than in rural England. But there was room for more improvement. He thought overdrinking of tea, especially tea that had stood long, had much to do with a low state of health in both countries. The housing problem was considered the chief cause by others, but that was equally acute in England, both in cities and rural districts. He did not think the two causes named afforded a satisfactory explanation of the state of affairs. In Ireland there was another factor—not nearly so extensive in England—viz., the emigration curse, which drew away the best blood of the race in its youngest and most promising members.

The decline of the population is an old story, said the president. During the awful time of the famine and fever Ireland lost 2,000,000 of her population. Following that came emigration, which in sixty years took away 4,000,000, mostly in the prime of life, leaving the oldest and least healthy at home and resulting in a birth rate the lowest in the world. After referring to what some expected England to do for her sister, the president asked whether full advantage had been taken of the Public Health Acts, Housing Acts, and other enactments. Are the public keeping an eye on the health committees and seeing that they do their duty? Are they promoting temperance, better housing, native industries? Are they helping the medical profession in their efforts to improve the health of the community? It is for want of knowledge that many things are neglected, and for that reason these congresses should be welcomed as opportunities of stirring up public opinion on points of vital importance to the public welfare.

At a meeting of the Society for Studying Disease in Children, held last month at Oxford, Dr. A. G. Gibson drew attention to enlarged veins in various positions met with in out-patients suffering from wasting anorexia and general debility. The commonest situation is on the front of the chest, but they are often seen on the back between the shoulders, under the chin, and on the temples. The veins are quite small and flush with the surface. They are not seen in all thin children, *e.g.* in those wasted with cerebral tumors, so probably they are dilated. In some there is obstruction, shown by dilated external jugulars, even in the upright position, which do not collapse on deep inspiration. Fourteen cases were recorded showing this sign, seven male and seven female, aged from four to ten years. In eight cases there was tubercle in the family. The left jugular was enlarged in fourteen, the right in twelve. Veins on the chest were seen in thirteen, on the back in two, on the temples in seven, under the chin in two. Downy hair on the back was found in six. The retraction murmur of Eustace Smith in ten. Small glands in nine. Tuberculous peritonitis was present in two cases and suggested in a third. In only one case was an anatomical explanation traced—that was in tuberculous peritonitis, in which a dilated left jugular had been noticed some time before death. At post-mortem a ring of small fleshy glands surrounded the left innominate vein, and sections of one of them showed tubercle bacilli. Other glands, caseating and with many bacilli, were found in the mediastinum. The cases seem to be such as Eustace Smith ascribed to tuberculosis of the mediastinal lymph glands, and it was suggested that in the absence of syphilis, lymphadenoma, or sarcoma, enlarged jugular veins which do not collapse on inspiration might, in conjunction with other signs, be of value in the diagnosis of early tuberculosis.

Very curious cases turn up at inquests, but rarely anything like one at Wolverhampton, on the 29th ult., which the coroner declared the most remarkable he had had before him in his fourteen years' office. It appeared that in April the deceased was found "smothered with blood," and said he had had a fall. The next day he had fits, and called in a doctor. Later he lost the sight of one eye and went to the eye infirmary. Afterward he was in the general hospital, and still later an out-patient. After death a small scar in the right temple was observed and a bullet in two fragments. There was fracture of the base of the skull and an abscess in the brain. The optic nerve was injured. It transpired that a revolver was found in his bed on the morning when he was found bleeding, and that he was a heavy drinker. A verdict of suicide while temporarily insane was returned. The curiosity is that this man had received severe injury to the brain and was under hospital and other treatment for weeks, but no one seems to have suspected the origin of his symptoms.

Yesterday the education minister received a deputation of medical men and others, headed by Sir V. Horsley and Sir L. Brunton, to urge the importance of all school children being examined by medical men, with a view of preventing consumption and other maladies, which might by careful inspections, they said, be ultimately as rare as leprosy. The minister promised to consider the matter, but referred to the cost as a difficulty. On Monday next the executive of the British Medical Association will wait on the minister, with the same object.

Yesterday at the Court of Common Council there was further discussion on the importation of food. The Chairman of the County Council attended and was welcomed by the Lord Mayor. The subject concerned all the metropolitan boroughs. One member deprecated any attempt to secure hasty legislation, and reminded the Council that on the previous evening the President of the Local Government Board had introduced a bill on the subject into the House of Commons. The debate was adjourned. In reference to milk supply, it was reported that in the city the adulteration was 7.5 per cent., as compared with 12.5 per cent. for all London. It might be well to take milk in the city rather than outside.

Mr. Henry Morris was yesterday elected president of the Royal College of Surgeons. Mr. Edmund Owen and Rickman Godlee were elected vice-presidents.

Dr. Henry Fraser goes to the Malay Straits as director of the Institute of Medical Research. He succeeds Dr. C. W. Daniels, who has returned to England to take an official post in the School of Tropical Medicine.

The death is announced of Dr. Wm. Robinson Hill, J.P., at the age of seventy, who practised for many years at Lymington, where he also took a great interest in the municipal affairs, for which borough he was a justice of the peace. He was physician to the local convalescent home. In earlier days he had served resident offices at Brompton Consumption Hospital and elsewhere. He was M.R.C.S., 1856, M.D.Edin., 1857.

OUR LETTER FROM CONSTANTINOPLE.

(From Our Special Correspondent.)

A NEW BACTERIOLOGICAL INSTITUTE—THE INDUSTRY OF PRODUCTION OF ROSE ESSENCE—A REMARKABLE CASE OF FECUNDITY—A MATERNITY HOSPITAL—SEA BATHS.

CONSTANTINOPLE, July 5, 1906.

THIS week the foundation has been laid for a new bacteriological institute in the Turkish metropolis. This institute is being elevated on the grounds of the Civil Veterinary College. It is intended to provide it with all the necessary materials and instruments for the production, in large quantities, of different kinds of antitoxic sera, sufficient in amount for the needs of the entire Ottoman Empire. The Sultan himself and his right hand in these matters, the present Minister of Agriculture, Selim Melhamé Pasha, take a very active interest in the new establishment. It is said that Abdul-Hamid offered out of his private purse a considerable sum for its construction.

The industry of rose essence production in the vilayet (province) of Hudavendighiar, in Asia Minor, an industry which brings in considerable sums annually into the State revenue and which inspired the Turkish Government with great hopes, has lately suffered very much from the fraudulent practices of the provincial distillers. It has been found out that the latter used to add to the pure essence of roses, in order to increase the bulk of the material sold, all sorts of extraneous matter. In consequence of this falsification, the ancient productive industry has lost much of its former reputation on the European markets. To remedy this state of affairs the competent authorities have taken energetic measures. Further frauds will be rendered almost impossible. The Governor of the named vilayet has received strict injunctions to watch over the practices of the distillers. Besides, a special commission has been sent to the place, with instructions to visit all the distilleries and to introduce the necessary improvements.

From the town Ipsala, near Dédéagatch, comes the news of a remarkable case of fecundity. A Turkish lady, who in May, 1904, was delivered of quadruplets, gave birth, last week, to two sons and a daughter. Mother and all the children are enjoying perfect health.

The Sultan has authorized the opening of subscriptions in order to gather the necessary funds for the construction of a maternity hospital in the Ottoman capital. Already over 1,000 Turkish liras have been subscribed by different officials, and the Padishah himself heads the list with a generous donation of several hundred pounds. This maternity hospital will be a real boon to the poorer population of

Constantinople, where unscrupulous and ignorant midwives hold their almost unlimited sway. These midwives have very frequently not the slightest notions of even the primitive rules of cleanliness and disinfection. The mischief that results is, of course, great. This will soon be remedied, as the maternity hospital which is to be constructed in the near future will be provided with all the necessary accommodations and a sufficient staff of medical men, as well as trained and qualified "*sages femmes.*"

The sea-bathing season has begun on the banks of the Bosphorus. The water of the latter being always clean, fresh, and cool, a bath in it is invigorating and acts beneficially on the whole system. The Ottoman Government has ordered this year that the pavilions constructed on the shores of the Bosphorus and the Marmora Sea for bathing purposes should be removed as far as possible from every source of contamination, and should be equipped with all the requirements of modern hygiene.

Progress of Medical Science.

Boston Medical and Surgical Journal, July 26, 1906.

The Diagnostic Significance of Decidual Tissue.—W. P. Graves cites several cases in which the microscopical examination of decidual tissue has been of importance or interest from a diagnostic standpoint, and concludes as follows: (1) The passage of a decidual membrane in a patient with symptoms of pregnancy and with a mass on one side, together with a history of flowing, is extremely significant of an extrauterine pregnancy, but cases do occur where this seemingly conclusive chain of evidence is not proof of an extrauterine gestation. (2) An ordinary miscarriage may be preceded by the exfoliation of a part or the whole of the decidua vera. (3) The pathologist who receives a specimen of decidual tissue should make his report with extreme reservation, to avoid the commission of a serious surgical blunder. (4) It may be impossible to differentiate, even with the greatest microscopical care, between an exfoliated dysmenorrheic membrane and the decidua of an extrauterine pregnancy, and the pathologist before committing himself to a diagnosis should insist on knowing accurately the history of the patient.

New York Medical Journal, July 21, 1906.

The Early Diagnostic Signs of Tabes Dorsalis.—C. S. Potts gives a general description of the early symptoms of tabes, without presenting, however, anything new. Various writers are quoted with reference to the frequency of different symptoms, but the percentage figures differ considerably. Potts calls attention to the fact that ataxia is not an essential symptom of tabes dorsalis, in many instances the disease being present for a considerable length of time before it appears, and more rarely in others it remaining absent. That persistent pain, especially of the lancinating and girdle types; of paroxysmal attacks of gastric pain, and vomiting, or other symptoms characteristic of the various crises which may occur in the disease; of painless swelling of one or more of the joints; of transient attacks of diplopia; of primary atrophy of the optic nerve, of paræsthesia, such as numbness, tingling, sensations as if walking on velvet, etc.; of difficulties in urination; loss of sexual power without apparent cause; and of physical exhaustion produced by slight cause, or any of the other symptoms above mentioned should arouse our suspicions, and lead us to examine for the presence of some of the symptoms belonging to the second class, viz., condition of the reflexes, pupillary symptoms, sensory paralysis, muscular hypotonia, etc. It may be stated that when not apparent, slight degrees of ataxia may be discovered by using delicate tests, such as standing on one leg, walking backwards, standing on the toes, performing fine movements with the fingers, as buttoning clothes, touching the end of the nose, etc., all being performed with the eyes closed.

Is Neuralgia a Functional Disease?—Based on the pathological findings in eight cases, A. Gordon offers the following conclusions: (1) The occurrence of degeneration of the peripheral nerve is frequent if not constant in neuralgia. (2) This nerve degeneration is very probably a primary condition, which as a neuritis assumes an ascending course and involves secondarily the Gasserian ganglion. Although this contention is still debatable, there is great probability in favor of the above view. (3) The blood-vessels undoubtedly play a certain role in the causation of a degenerative state of the peripheral nerves. (4) It is difficult if not impossible to draw a sharp distinction between neuritis and neuralgia, as accumulated facts show an anatomical basis in the latter affection. (5) In view of these anatomical facts, it is highly important to remove surgically a nerve affected with so called neuralgia as early as possible after a short trial of medical treatment is given.

Journal of the American Medical Association, July 28, 1906.

Generalized Blastomycosis.—C. Christensen and L. Hektoen give detailed histories of two cases of disseminated blastomycosis. In both the onset was sudden and without the presence of any chronic external lesion that might be regarded as the primary localization. In the first case, the cutaneous and subcutaneous lesions developed simultaneously after an acute febrile attack, and suggest the lungs as the portal of entry of the infection. In the second case, the localization of the infection seems to have been in the deeper tissues before the subcutaneous invasion. The authors suggest the advisability of experiments to determine whether the organisms are easily conveyed by air currents when dry, whether they retain their vitality and infectiousness after drying and whether or not they are carried in minute droplets of sputum. The peculiar predilection for the skin possibly indicates an important avenue of escape of the germs, it may be to new hosts. The authors also suggest the possibility of infection of skin lesions by way of the blood current and not always, as seems to have been supposed, by direct implantation from without. No effective treatment has yet been devised. In these cases the authors tried a sterile vaccine prepared from the blastomycetic organism, with the idea of stimulating opsonic action according to the method of Dr. A. E. Wright. Unfortunately, the patients passed from their observation, leaving the hospital before any definite conclusion of value could be drawn as to the result of this treatment. Work is now being done to devolop certain methods by which the effect of the blastomycetic vaccines can be tested *in vitro*, so as to furnish some guidance in the treatment of the disease.

Interstitial Gingivitis Due to Autointoxication.—E. S. Talbot discusses the subject of interstitial gingivitis from intoxication as shown by the blood pressure and urine examinations. The alveolar process, he holds, is supplied by end arteries, and like other organs thus supplied its nutrition is quickly disordered by vascular disturbance. Moreover, on account of the rigid tissues surrounding the arteries, the toxin-containing blood sets up an irritation more quickly and inflammation resulting in bone absorption occurs the earlier. Everybody suffers more or less from interstitial gingivitis, and as the excretory organs fail with age the condition is apt to become more pronounced. From an examination of the urine in fifty cases he finds evidence of renal insufficiency or excessive suboxidation products producing renal strain. Study of the tables shows two conditions present: First, autointoxication due to intestinal fermentation and faulty elimination, as shown by the indican; and second, kidney overstrain and renal insufficiency due to hepatic insufficiency. The liver failing to eliminate toxins, kidney overstrain causes the blood to become surcharged with toxins and acidity. Cardiac and arterial degenerative changes with cardiac hypertrophy and vascular disturbances and insufficient supply of blood are the consequences. Just what these toxins are is not determined, but it is supposed that they are unoxidized products of metabolism, such as poisonous ammonium salts, xanthin, etc., which can, when injected in the blood of small animals, produce kidney disease. They probably act in different ways on the vasomotor nerves, the heart muscle and the end arteries. Talbot has also investigated the blood pressure, in these cases which plays its part in helping to set up the irritation, and he points out that the gums are likely to be first involved in various toxic affections, owing to the peculiar position of the end arteries and bone and their increased liability to be affected after the completion of growth. He enumerates a number of symptoms and conditions, of which interstitial gingivitis may be a significant prodrome, such as hypochondria, neurasthenia and Bright's disease.

Palliatives for Hay Fever.—Solomon Solis-Cohen reviews the present methods of treatment of hay fever. He considers first the suprarenal preparations, and states that for some individuals and in certain seasons the systemic action of these preparations is sufficient to induce and to preserve comparative comfort. He states that they must be absorbed from some mucous membrane to be effective and that they are practically useless when given by the stomach. He discusses the Dunbar serum, which he considers a distinct addition to our therapeutic resources in the treatment of this disease. Both pollatin and suprarenal preparations should be snuffed into the nose or insufflated the first thing in the morning, and if this is thoroughly done and if the individual remains recumbent for ten or fifteen minutes afterward such an application will usually suffice for a whole day. In the internal treatment of this condition he recommends a combination of hyoscine hydrobromate, camphor, and sugar of milk, or a combination of atropine, camphor monobromate, and Peruvian balsam.

When possible patients should go to an immune region. Dark glasses are often useful. The diet must be simple, and on the whole sparing, omitting pastries and sweets.

Routine Urine Examinations.—M. H. Fussell insists on the value of the routine examination of the urine. Even though albumin and casts do not always mean nephritis, their presence in the urine indicates that a vital organ is at fault, and that this fault must be duly considered in the diagnosis, prognosis, and treatment. There are other conditions also to be made note of which are of the greatest importance, such as the presence of glucose, of pus, of blood and persistent or intermittent excessive amount, all of which are to be taken note of in the routine examination. He gives, as illustrating his view, his own experience for the past eighteen months, in which he has examined the urine of 763 patients, and found abnormalities in 15 per cent. He gives abstracts of the case histories of a few of these which prove, he thinks, that it is only by a routine examination that we can make more than a tentative diagnosis in 15 per cent. of all patients treated. To examine the urine only when symptoms point to a genitourinary disease is to miss the diagnosis in many important cases in time to be able to give them benefit by treatment.

American Journal of the Medical Sciences, July, 1906.

Belladonna Poisoning Due to Belladonna Plasters.—C. M. Dolan reports three cases of poisoning due to belladonna plasters. When the writer first saw one of these patients she was in a highly excitable state. The pupils were dilated, the mouth was dry, and a diffuse erythematous rash was noted on the face, shoulders, and chest. The poisoning was due to a small belladonna plaster that had been placed on her chest. The plaster was removed, and in a few hours the symptoms subsided. Atropine is rapidly eliminated, and the removal of the belladonna plaster in these cases will probably be rapidly followed by a cessation of symptoms, as a general rule. Any further treatment would consist in the administration of the physiological antidotes of atropine.

A Bacteriological Study of the Certified Milk of Philadelphia.—A. H. Stewart reports the results of the examination of samples of certified pasteurized milk. Fifty-six per cent. of these samples were found deficient. Fifty-seven and four-tenths per cent. of the samples of certified milk were below the standard. The writer declares that one examination of milk per month is not sufficient. More frequent examination should be made in the summer than in the winter. Examinations for pus and streptococci should be made before the milk is sold. Extra expenses connected with the examination should be abolished at once. Milk should be delivered the same day it is brought to the dealer. Refrigerator cars are necessary. Covered milk buckets should be used in all dairies. A campaign of education should be started at once to teach purchasers of milk that the milk they receive is usually two days old. The milks which are reported here are probably among the best produced in this country.

Hepatoptosis or Floating Liver.—J. F. Binnie says that hepatoptosis may be partial or complete. This condition is commonly associated with ptosis of other abdominal viscera. Various causes are enumerated: Increased weight of the liver, cholelithiasis, laxity and elongation of the hepatic ligaments, trauma, failure of support from below by the intestines and abdominal wall, malnutrition, and neurasthenia. Tight lacing is sometimes cited as a cause, but this is incorrect. A snugly-fitting corset supports the liver. This affection is undoubtedly far more common than is usually supposed. The symptoms of hepatoptosis vary with the degree of the affection. Constipation and tympanites are almost always present. The subjective symptoms are those of neurasthenia. In the treatment of such cases attention should be paid to nutrition, and the muscles should be built up by massage and appropriate exercises. Any increase of the ptosis should be prevented by supporting the abdomen with a well-fitting corset or belt. Operative aid is indicated in severe grades of ptosis.

The Lymphatic Drainage of the Pharyngeal Tonsil.—George Bacon Wood states that the pharyngeal tonsil is essentially an organ of early life. The writer injected the pharyngeal tonsil, using essentially the same technique as that used in injecting the faucial tonsils. The process is very difficult. In about six trials, only two good injections were obtained. The writer describes his work as follows: "In the first injection a small retropharyngeal gland was present and was deeply injected. One gland of the posterior group of upper deep cervical glands was also injected, but the connecting lymph trunk was not found. In the other specimen the lymphatic vessel, after a careful dissection, was traced from its exit at the lower part of the pharyngeal tonsil to its entrance into a little gland of the posterior group of the upper deep cervical glands. The route of this lymph vessel is as follows: Running posteriorly from the lower part of the pharyngeal tonsil, the vessel penetrates through the posterior pharyngeal wall, entering the retropharyngeal space; then it runs downward and outward just below the insertion of the rectus capitis anticus major, and between this muscle and the bodies of the cervical vertebræ: still running obliquely downward and outward, it passes beneath the sheath of the great vessels of the neck until it reaches a position almost opposite the posterior border of the sternocleidomastoid. It then turns directly outward, and enters one of the small glands situated just below the tip of the mastoid, along the posterior border of the sternocleidomastoid muscle. The three most important sources of infection of the cervical lymph glands are the gums, the faucial tonsils, and the pharyngeal tonsil. Infections entering through the pharyngeal tonsil involve the lymph glands just beneath the posterior border of the sternocyldomastoid. Clinically, the enlargement of these glands may be diagnosed by a diffuse swelling of the upper part of this muscle.

Recent Advances in the Physiology of the Digestive Organs Bearing on Medicine and Surgery.—Walter B. Cannon speaks of recent studies which show that neither ether, nor the cooling of the viscera, nor the drying, in abdominal operations, checked to any marked degree the onward passage of food. On the contrary, even the most gentle handling within the peritoneal cavity was followed by absolute cessation of gastric peristalsis. The onward passage of food was retarded by the fingering of the stomach and intestines. These observations were made on normal, vigorous animals. There is a very close relation between the functioning of the alimentary canal and the general state of the body. There also exists an interrelation of different parts of the canal which unites the digestive processes in an orderly series of successively dependent events. In relation to the former statement, it has been proved that depressing emotions not only check the movements of the stomach and intestines, but also inhibit the secretion of the gastric juice. Chewing food that is relished starts the flow of gastric juice. The presence of gastric juice in the duodenum causes the flow of bile and the pancreatic secretion. The pancreatic secretion stimulates the formation of kinase, which activates the trysinogen. On the motor side of digestive activities, the presence of material in the stomach normally starts gastric peristalsis. Acid in the stomach seems to be the cause of the opening of the pylorus through which the food passes. Acid food in the duodenum closes the pylorus and originates segmenting movements to churn together the food, pancreatic juice, and bile. The masses are carried forward by peristalsis, and in new situations their presence occasions segmentation. Many problems are yet unsolved, and, as the writer states, the need is for more men to look for the hidden things.

The Lancet, July 14, 1906.

Microbic Cyanosis.—An unusual case is reported by G. A. Gibson and C. C. Douglass, whose patient was a woman of thirty-six years, subject to headaches with giddiness and faintness and a peculiar change in the complexion. This latter change had been a matter of gradual development during a period of two or three years. Various examinations were made of the bodily secretions and excretions, and it was found that in the blood there was an organism present, either the *Bacillus coli communis* or some very closely allied organism of the colon group which was obtained in pure culture from the blood. It was apparently without the power of producing nitrites *in vitro* in peptone water, but it was impossible to say what the result of its chemical activity within the blood might be. It seemed to the authors very desirable that these observations should not be taken as final, but a provisional reading of the case seemed to be this: That the original source of mischief lay in the bowel, that a systemic infection had taken place, that nitrites were being constantly produced in the body in varying amounts (thus possibly explaining the varying degrees of cyanosis), and, finally, that nitrites acting on the hemoglobin constantly kept a varying amount of it in a state of methemoglobin—a condition in which oxygen was very firmly united to the hemoglobin molecule and would not separate from it for the needs of the body cells. They add that the condition belongs to the group of affections often termed false cyanosis. At the time the case was reported the patient's condition was practically

unchanged. The obvious therapeutic indications were considered to be intestinal antisepsis combined with the abundant use of diluents.

Buboes and Their Significance in Plague.—A series of cases is reported by W. Hunter, who gives also an analysis of the studies (as regards buboes) on 1,000 fatal cases of bubonic plague. He notes that all bubonic swellings show the presence of extraneous microorganisms. The infection with other bacteria would appear to occur early. The microorganisms most frequently found present are staphylococci, streptococci, the bacillus coli, and its varieties. These organisms exert a deleterious action on the *Bacillus pestis,* and in advanced buboes are found present even in greater numbers than the bacillus pestis. It would appear to be of importance to determine what part the *Bacillus pestis* actually takes in the formation of the bubo. In the author's opinion it is extremely doubtful if the plague bacillus can be held responsible for the full development of the bubo; in fact, his own experience leads me to believe that buboes are the result of the local growth of the *Bacillus pestis* plus pyogenic bacteria, and the latter by their more active growth cause a full development of the bubo with all its typical pathological appearances, and eventually crowd out the actual bacillus pestis itself.

Hints to the General Practitioner on Eye Strain and Its Symptoms.—J. Hinshelwood divides the symptoms of eyestrain into local and general. The former include headache, uncomfortable sensations in the head, giddiness, insomnia, congestion of the eye and lids, blinking, and retinal asthenopia. The latter is often met with in neurasthenic conditions of the nervous system, and the treatment must be directed to the improvement of the general condition. There is often an intestinal autointoxication. Local treatment such as rest, protection from bright light, and the use of ocular analgesics such as holocaine and dionine will afford a certain amount of relief, but no permanent benefit is assured until the general system is set right. In general the author says that in treating eyestrain it is important to impress on the patient that more is required than the prescription of suitable glasses. The patient must be instructed to use his eyes in an intelligent way so as to throw a minimum of strain upon them and allow the function of vision to be exercised under the most favorable conditions. Attention must be given to the length of time the eyes are used for near work, to the size of the objects looked at, and to proper illumination. The intelligent cooperation of the patient is necessary in such cases to bring about a satisfactory result. Any local affections of the lids, the passages, or of the eye itself, of course require careful treatment. A patient will not be able to use his eyes with comfort until all pathological conditions of the eye itself, of the lids, and the tear passages have been removed.

British Medical Journal, July 4, 1906.

The Relation of Ulcerative Colitis to Dysentery.—A. E. Carver believes that there is some evidence that the bacillus of Flexner and Shiga occurs in cases of colitis. In three cases of ulcerative colitis, a positive result was obtained in one and a negative in two, with reference to agglutinative power. Flexner has already pointed out that the agglutinative reaction is obtained comparatively early in the course of the disease in dysentery, and that it disappears at an early date. This Carver considers as scarcely to be wondered at when one appreciates how great the chances are of a secondary infection occurring from the large bowel, and it is quite possible that the nature of such secondary infection may determine the clinical variety of the colitis. Reference is made to several epidemics of acute colitis. In some the symptoms were practically identical with those of acute bacillary dysentery, as were also the pathological lesions. The author believes that such articles as infected blankets (from bacillary cases) may be the medium of provoking outbreaks of colitis.

The Effect of the X-Rays Upon the Leucocytes in the Blood and Bone Marrow in the Leukemia.—According to R. J. M. Buchanan the action of the rays is of a twofold nature. First, they inhibit overproduction in the marrow; and second, they exercise a destructive effect on the leucocytes themselves. This is very evident in the blood count. Coincidently the spleen diminishes in size. In the blood the large, finely granular myelocyte, and the large, coarse granuled eosinophile myelocyte, which give the blood in leukemia so distinctive a character by their presence, and which are not usually to be found in normal blood, are rapidly reduced in numbers, and have been said to disappear entirely. The author notes that in examining stained specimens from cases which have not been exposed to the rays the large myelocytes have been present in great numbers. After exposure the polymorphonuclear cells appeared to be the most numerous; then the transitional, and least numerous of all, the myelocytes, large and small. This condition is quite evident, even without a differential count. Moreover, in all the cases in which the myelemia has been marked, nucleated red blood cells have been present and easily detected in stained specimens. After the ray treatment no nucleated red cells have been found. The author's main conclusions are summarized in the two propositions above stated.

Total Laryngectomy for Recurrent Epithelioma of the Larynx.—The patient of S. White was a man of sixty-four years who had been hoarse for a long time. A growth was discovered on the cord and removed after a thyrotomy. Immediate relief was soon succeeded by laryngeal stenosis requiring tracheotomy. Some two and a half years were passed comfortably, a large tube being worn, when bleeding began from the tracheotomy wound. An ulcer was found running upward from the wound. Cuttings from its edge showed typical epithelioma tissue. Laryngectomy was done (operation detailed) and the patient made a fairly prompt recovery. Six months later he could swallow well, was in good health, had no respiratory difficulty, and could carry on conversation in a loud, sibilant whisper by drawing air through his nose into his pharynx and expelling it buccally.

Berliner klinische Wochenschrift, July 9, 1906.

Retrograde Currents in the Esophagus as a Cause of Coating of the Tongue.—Kast, by giving a number of persons capsules containing lycopodium, was able to demonstrate the existence in the esophagus of currents proceeding from the stomach toward the mouth. The persons experimented upon swallowed the capsule in the evening and one or two hours later the mouth was thoroughly rinsed out. The next morning the mouth was again rinsed out and the water used examined microscopically for the presence of lycopodium grains. In six out of eleven cases the test substance was found in the mouth the morning after the dose had been swallowed. The author believes that the rhythmical alterations of pressure in the thorax due to the respiratory movements, the pulsation of the heart and aorta, and the movements of the diaphragm and the body as a whole, cause the walls of the esophagus to rub against each other in such a way as to produce an upward current in the capillary column of fluid existing in the collapsed tube. He then goes on to express the theory that the manifestations of heart burn may be explained by the entrance into the esophagus of portions of hyperacid gastric contents, and to suggest that the phenomena of coating of the tongue and oral fetor that accompany disturbances of gastric digestion are dependent upon this passage upward of material from the stomach.

Münchener medizinische Wochenschrift, July 10, 1906.

Experimental Observations on Framboesia Tropica in Monkeys.—Neisser, Baermann, and Halberstädter while studying syphilis by means of inoculation experiments carried out in Java also took up the matter of the position of frambesia tropica in regard to syphilis. They investigated the possibility of the transmission of the disease from man to monkeys, from monkey to monkey, the result of inoculations with material from the organs of frambesic monkeys, and the inoculation of frambesia and syphilis in the same monkey. These experiments, though not carried out on a very large number of animals, lead the authors to conclude that frambesia is a disease which can be transmitted from man to the higher and the lower monkeys, and that it is transmissible from monkey to monkey. The positive result of inoculations with material from infected glands and organs shows that the poison of frambesia is disseminated generally throughout the entire body. The experimenters also succeeded in obtaining successful inoculations with both syphilitic and frambesic virus in the same animal, and they believe, therefore, that the two diseases are etiologically different, though the similarity in their clinical manifestations suggests the possibility of some fundamental resemblance.

Oral Eczema.—Galewsky states that certain people are especially susceptible to some of the ingredients used in the popular mouth washes and toothpowders, and that in these the use of such preparations is sufficient to evoke more or less severe eczema of the lips, angles of the mouth, and chin. He reports sixteen instances of this sort in which the skin was reddened and scaly, there were painful rhagades in the angles of the mouth, the mucous membrane of the lips was swollen and tender, and all movements of the lips were painful. Those who are susceptible to irritants of this sort are people with very delicate skins, especially if they suffer from a tendency to seborrhea, and in individuals with a general eczematous diathesis. A study of the ingredients in the various mouth washes used showed that oil of peppermint and oil of cloves seemed most likely to be responsible for the condition, though other substances employed, such as tincture of arnica, salol, formaldehyd

etc., might also come into question. It appears that the volatile oils, and especially the terpenes contained in these, are most likely to cause eczema of this variety. The treatment consists in stopping the use of the irritant, and in the application of bland ointments or lotions.

The Origin and Prophylaxis of Chronic Diphtheria.—Grunwald has observed two cases of this affection, which must be distinguished from these instances in which individuals simply serve as chronic bacilli carriers. Previously only six cases of chronic diphtheria have been reported, and the author describes one of his cases in detail. The patient was a man of forty-nine years, who presented a membraneous inflammation of the tonsils and soft palate which had begun four months before. The condition had been considered to be due to syphilis, and had been energetically treated on this basis, but diphtheria bacilli were found in the membrane, and under a nonirritating local treatment recovery finally followed. The author considers that chronic diphtheritic inflammations of this sort may be due to the nonuse of antitoxin during the acute stages of the disease, and to the resort to topical or general remedies, such as mercury, which are likely to keep up a condition of local irritation or to impair an already weakened tendency to recovery.

Deutsche medizinische Wochenschrift, July 5 and July 12, 1906.

The Prevention of Baldness.—Lassar says that in order to combat baldness successfully it is necessary to begin as promptly as possible after it is first noticed that the hair is beginning to fall. Healthy hairs, he says, do not come out, and if hairs are found on the pillow, on the clothing, or in the hairbrush, the indication is given for beginning the treatment. One of the most important, yet very generally neglected prophylactic measures, consists in frequent ablution of the head, a measure that is still considered injurious by many people. On the contrary, frequent shampooing and rubbing of the head is the best preventative of baldness. Another feature on which the author lays much stress is the necessity for cleanliness in all utensils used in the barber shop or in private. Actual baldness cannot be cured, but a great deal can be done to prevent its onset by properly treating the tendency to falling of the hair. A course of treatment is outlined, of which the following are the most important features: Daily shampooing with soap and hot water, followed by drying and the application of a 1-1000 solution of bichloride of mercury. This is allowed to evaporate, and the scalp is then rubbed with a 1-400 solution of thymol or naphthol in alcohol. Finally, an ointment is applied containing one part of salicylic acid, two of tincture of benzoin, and fifty of vaseline. In obstinate case the treatment is begun by the application of tar liniment, which is removed ten minutes later with the soap.

Potato Dishes for Diabetes and Obesity.—Sternberg recommends the following method of preparation of potatoes for use in the dietary of diabetic patients or persons under treatment for obesity. The potatoes are peeled and grated with a coarse grater, the pulp being allowed to fall into a vessel containing water. After standing for a time it will be found that the potato starch has separated from the fibrous material and has settled at the bottom of the receptacle. The fibrous material in the upper layers of the fluid is poured off and is strained through cheesecloth, most of the adhering starch passing through into the filtrate. The solid mass remaining on the cloth can then be utilized as the groundwork for the preparation of a great variety of dishes with which eggs, cream, milk, etc., can be combined. Articles of food prepared in this way contain very little carbohydrate, but retain the taste of potato, which is often a craving among patients who are denied the vegetable, and are also very satisfying, although the nutritive value of the potato fiber itself is, of course, very slight. The author has found this method of preparation very useful, and he gives the recipes for a considerable number of dishes.

The Origin of Pulmonary Tuberculosis.—Schlossmann and St. Engel agree with Behring that pulmonary tuberculosis is usually a late manifestation of an infection contracted during infancy or childhood. They describe the following experiment, undertaken in order to demonstrate the possibility of intestinal infection under conditions which preclude any participation of inhalation in the process. Young guinea pigs were etherized after five or six hours of starvation and their stomachs exposed by a laparotomy. A small amount of a tubercle bacillus emulsion was then injected into the organs under the most rigid precautions to avoid any peritoneal contamination with the organisms. Tubercle bacilli are found in the lungs of such animals a few hours after the bacilli have been injected together with milk or cream, and guinea-pigs in whose abdominal cavities a piece of the lung of such an animal is inserted a few hours after the original inoculation, without exception die of tuberculosis. The authors believe that the bacilli traverse the intestinal wall, and passing through the mesenteric lymph nodes, which are more permeable than the glands in other portions of the body, reach the thoracic duct and together with the chyle are poured into the venous blood stream, from which they readily reach the lungs. They are of the opinion that in most cases tuberculous infection takes place in this way during infancy or childhood.

Further Observations on Spinal Anesthesia.—Freund, who has used this method extensively, speaks highly of it and expresses the view that it not only will not disappear from the operating theatre, but may even become one of the most important means of anesthesia. In the period from May, 1905, to June, 1906, he has employed the method in 209 cases, and he believes that as the experience of operators increases the drawbacks heretofore considered inherent in the method will be found to diminish. One point on which he lays stress is that the injection be made exactly in the middle line of the spinal canal and as high up as possible. If the anesthetic fluid be injected laterally it is apt to enter a series of blind canals in this situation and is prevented from exerting its full potency. For gynecological operations the author recommends that after the injection the patients be placed for twenty minutes flat on the back with the pelvis elevated at an angle of 20 to 25 degrees. By doing this proper distribution of the area of anesthesia is secured, but its extension too high up when the patient is put in the Trendelenburg position is prevented. In making the injection it is preferable not to allow more than 4 c.c. of spinal fluid to escape. Another point on which the author lays stress is that no attempt shall be made by pricking or pinching to determine the extent of the anesthesia before the operation is begun, as he considers that in nervous patients the success of the method may be impaired by such procedures. The patients comprised in this series ranged from eighteen to seventy-three years of age, and the operations performed covered the usual routine of gynecological work. One death is reported, that of a woman of seventy-three, with a fibroid uterus, who died eight minutes after the spinal injection and before the operation had been begun.

The Demonstration of the Spirochaeta Pallida in the Preputial Nerves.—Ehrmann has succeeded in demonstrating this parasite not only in the immediate neighborhood of nerve fibers of the prepuce in cases of chancre, but also in the interior of the fibers themselves. He, therefore, concludes that the spirochetes are able to travel along the lymph spaces of the connective tissue to the neurilemma and through this. It, therefore, appears highly probable that the spirochetes under these circumstances travel centrally along the nerve fibers, and it does not seem impossible that, like the causative agents of other diseases, such as hydrophobia and tetanus, they may be able to ascend along the course of the nerve tracks and later on give rise to the parasyphilitic affections, especially tabes. The fact that the latter disease usually begins in the lumbar cord appears to corroborate this view, since it is well known that the virus may remain latent for decades in localized depots.

Chauffeur's Fracture.—Mühsam reports two instances of this injury, which is the result of backfiring during the act of cranking the motor. In the one instance the fracture was a simple one of the lower end of the radius attended by but little displacement, but in the other there was a very marked degree of deformity owing to longitudinal dislocation of the fragments. The ulna was also somewhat displaced toward the radial side. According to Lucas-Championnière this type of injury may be either direct or indirect, according as the fracture is caused by the impact against the forearm of the crank handle, or is the result of forcible hyperextension of the hand still grasping the handle. In the latter case the severity of the injury and amount of displacement produced depend largely on the point in the circumference of the circle described by the crank at which the sudden recoil takes place, there being less danger of dislocation if the backfiring occurs when the hand has begun the upward movement. The prognosis and treatment are the same as for ordinary fracture of the radius.

Syphilis in the Pathogenesis of Tabes Dorsalis.—Gino de Pascalis believes that syphilis determines a degeneration, more or less rapid, of the nervous elements, and this is the primary fact in the pathogenesis of tabes dorsalis; meningeal alterations and vascular changes come on as a reactive process solely. In the central nervous system reactive processes give increase of connective tissue, and of substitution in the neuroglia. When any morbid cause determines a change such as brings about a slow sclerosis of tissue in an organ, with an increase of interstitial tissue, the pathogenic agent influences at the same time the tissue of the organ itself and its framework.—*Il Policlinico.*

Book Reviews.

HANDBOOK OF SURGERY. By GEORGE BURNSIDE BUCHANAN, B.A.Cantab., M.B., C.M., F.R.C.S. (Glasg.), Assistant Surgeon, Western Infirmary, Glasgow; Assistant Surgeon, Glasgow Cancer Hospital. New York: William Wood & Company, 1906.

FOR some time there has been a demand for a short Handbook of Surgery; a book which, while small in size, should cover the entire subject and at the same time be reliable. The present volume is an attempt to supply this want, and from a careful examination of the book we think the author has been unusually successful. Of course the book is, to a large extent, a compilation, it could not well be otherwise; but the author seems to have chosen his authorities with care and wisdom, and the result is an attractive volume which will be of service to all who wish to revise the subject before presenting themselves for examination. With very few exceptions no attempt has been made to give full descriptions of operations; and the specialties of Eye, Ear, Nose, Throat, and Gynecology have been omitted except in so far as they trench on the domain of General Surgery. We have found a few minor inaccuracies, but they will be readily detected by the student, and in no way interfere with the general value of the work. The book is well arranged and written, clearly printed, attractively gotten up, and is extraordinarily complete. It is what it professes to be—a Handbook of Surgery—and is in no way to be confounded with a Quiz Compend.

UEBER DAS WESEN UND DIE VERBREITUNG DER WURMKRANKHEIT, ETC. Unter Mitwirkung von Dr. LÖBKER und Dr. HUGO BRUNS, bearbeitet im kaiserlichen Gesundheitsamt. Berlin: J. Springer, 1906.

THIS German book presents a complete history and an account of the geographical distribution of ankylostomiasis and is of importance as representing the results of a special governmental investigation into this subject, which was stimulated by the spread of the disease among the coal miners of Germany. Both the biological and clinical features of the infection are discussed in great detail. In attempting to clear up the etiological factors of this disease, it became apparent that the increase in the number of cases seemed to coincide with the greater amount of moisture which prevailed in the mines as the result of more frequent sprinkling in order to reduce the chances of explosion from coal dust. This precaution could, of course, not be stopped, and so other means had to be devised for checking its spread. It was found that the disease could be most efficaciously combated by making frequent examinations of the stools of the suspected individuals, and also by providing proper sanitary receptacles for the reception of fecal matter, so that the latter could not be distributed through the mines. The latter should also be thoroughly disinfected at frequent intervals. The good results obtained by insisting on these prophylactic measures is shown by the fact that in one district alone the number of cases was reduced in two years by 83.14 per cent.

THE DISEASES OF THE NOSE AND ACCESSORY SINUSES. By H. LAMBERT LACK, M.D., F.R.C.S., Surgeon to the Throat Department of the London Hospital and Lecturer on Diseases of the Throat to its Medical College. London: Longmans, Green & Co., 1906.

THIS volume is an elaboration and further studies along the line of the essay by the author on Pathology, Diagnosis, and Treatment of the Inflammatory Affections of the Nose and its Accessory Sinuses and Air-cells, which was awarded the Jacksonian prize in 1899. By this revision the general ground covered has been brought up to date. The author gives a systematic account of those topics on which there has been no recent controversy and upon which no great divergency of opinion exists at the present time. He does not avoid disputed questions, and though very tolerant of the views of other writers, he does not hesitate to express his personal convictions in definite terms. A useful feature of the book is the addition at the end of each chapter of a short bibliography containing references to the more important recent contributions to the several topics considered. Footnotes to minor articles are plentifully scattered throughout the work. On the whole, we regard the book as containing valuable material, well analyzed and put together in an attractive, readable form. Books on rhinology have followed each other so rapidly in recent years that there has necessarily been much duplication. Specialists are naturally curious to note the attitude taken by each new author on the questions of the day. Two of these may be referred to. Concerning the serum treatment of hay fever, the author declares that at present there is not enough evidence to support the claims made for it. In passing, we would especially commend the temperate tone of the chapters on hay fever and asthma. In regard to the submucous resection of the septum nasi, the author says that while the method has the advantage of simplicity of after-treatment and the avoidance of any retention apparatus, it is difficult to perform and requires much time. He does not consider it applicable to every case of septal deflection. These are put forth, however, only as personal opinions. The book is to be commended from every point of view.

GREEN'S ENCYCLOPEDIA AND DICTIONARY OF MEDICINE AND SURGERY. Vol. I. Aachen to Brain. Edinburgh and London: William Green & Sons, 1906.

THIS is the first volume of what promises to be a very satisfactory encyclopedia of medical science, occupying the place in Great Britain which is filled in this country by the Reference Handbook of the Medical Sciences. It differs from the latter, however, in the general arrangement and treatment of the subjects and also in the dictionary feature. The titles are arranged alphabetically, and interspersed with the longer articles are many terms which are simply defined in words or by a cross reference to a longer article in which the subject is more fully treated. The dictionary feature is, however, limited to definitions, etiology and pronunciation not being indicated, and accepted differences in spelling and form being ignored. The system of cross references is very complete, not only in connection with the dictionary titles but also in the longer articles. In the latter, also, ready reference is facilitated by a short table of contents, indicating the page on which each separate topic is treated. The work is apparently supplementary or complementary to the Encyclopædia Medica, the publication of which was completed two years ago. In some cases the subjects have received new treatment in the present work, in others the article has been transferred from the older treatise to the new one, supplemented, perhaps, by a new section, marked by brackets.

The editor of the Encyclopædia and Dictionary is Dr. J. W. Ballantyne. In addition to the editorial supervision, he is responsible for the dictionary material, has written most of the smaller articles of thirty lines or less, and has added the new matter, where necessary, to the longer articles transferred from the earlier work. The names of the authors are not appended to the articles, but are given in the table of contents. The list is too long to be given here, but it contains the names of many British authorities in the various departments of medicine. Among the important titles treated in the present volume are: Abdomen, Abortion, Accommodation, Acne, Actinomycosis, Adrenal Glands, Air, Alcohol, Alkaloids, Amputations, Anemia, Anesthesia, Aneurysm, Ankle-joint, Anthropology, Appendix Vermiformis, Arteries, Aseptic Treatment, Balneology, Bladder, Blood, Bone Diseases, and Brain. The illustrations are not numerous, but are apt and well made, several being in the form of colored plates. The writers have done their part well, and under the capable editorial supervision of Dr. Ballantyne have contributed to make a work of superior quality and a valuable addition to medical literature. The encyclopedia will be completed, according to an intimation in the preface, in 1908, and will be followed by a supplement to the Encyclopædia Medica, which will also serve as supplementary matter to the Encyclopedia and Dictionary.

INTRODUCTION TO MATERIA MEDICA AND PHARMACOLOGY, including the elements of Medical Pharmacy, Prescription Writing, Medical Latin, Toxicology, and Methods of Local Treatment, by OLIVER T. OSBORNE, M.A., M.D., Professor of Materia Medica, Therapeutics, and Clinical Medicine in the Yale University; ex-President of the American Therapeutic Society; ex-Chairman of the Section on Pharmacology and Therapeutics of the American Medical Association. Philadelphia and New York: Lea Brothers & Co., 1906.

THE title of this little book gives an exact idea of its contents. Medical students will do well to read this volume before beginning the study of Materia Medica and Therapeutics; by so doing they will lighten their future labors and also obtain information on many little points often omitted in the text-books.

CHRISTIANITY AND SEX PROBLEMS. By HUGH NORTHCOTE, M.A. Philadelphia: F. A. Davis Company, 1906.

THERE has been no dearth of literature on sex problems during the past decade. The present volume is an important contribution to this subject, and will prove of real help to physicians and parents. Its semireligious and philosophical tone are liable to lessen its sphere of usefulness, as by the time a man understands and appreciates this style of literature he is generally of an age when he has settled for himself the problems that this book is intended to solve. There are several valuable chapters in the work, and of the various books on this subject written by laymen this is easily the best.

Society Reports.

NATIONAL ASSOCIATION FOR THE PREVENTION OF TUBERCULOSIS.

Second Annual Meeting, Held at Washington, May 17 and 18, 1906.

(Special Report to the MEDICAL RECORD.)

(Continued from page 118.)

PATHOLOGICAL AND BACTERIOLOGICAL SECTION.

DR. EDWARD R. BALDWIN OF SARANAC LAKE, CHAIRMAN.

Thursday, May 17.

Tuberculous Meningitis.—Dr. D. J. McCARTHY of Philadelphia read this paper. He said the text-books implied there was but one pathological type—that with the miliary tubercles in the meninges. Dr. McCarthy's studies had shown a number of deviations from the normal type. The first deviation was the so-called tuberculosis *en plaques*, a condition in which foci of a chronic proliferative tuberculous process were scattered over the surface of the meninges with fibrous connective tissue present without any tubercle bacilli in this material. Until recently this was thought to be an incurable disease, but his study of these cases showed distinct evidence of previously healed processes in the meninges. In these cases of tuberculosis involving small areas, the healed meninges never showed the presence of the tubercle bacilli except in one case. He called attention to the fact that in cases of miliary tuberculosis, independent of its existence at the base of the brain, hydrocephalus was a factor independent of obstruction of the lymphatic circulation. Its presence depended upon some disturbance of the circulation between the choroid plexus and the cerebral ventricles. Another type he referred to was the mixed septic tuberculous meningitis. He had seen this type develop in lower animals, the cultures showing streptococci in association with the miliary tuberculosis. Subacute leptomeningitis occurred very frequently, in a large number of the cases going on to autopsy. In seventeen out of seventy-eight autopsies, a granular condition over the base of the brain, with distinct evidences of thickening of the meninges was demonstrated. The microscopical examination showed a proliferative condition of the meninges, with an overgrowth of lymphatic elements, and a recent deposit of fibrin. This type did not ordinarily produce symptoms. Again, there was a localized meningitis of the brain from a blood infection, one case in particular, seen at the Phipp's Institute, being of particular interest; here there was a localized tuberculous meningitis in one hemisphere, this localization being along the distribution of the middle cerebral artery. The temperature, which had been but slightly above 100°, went suddenly to 101°, and then developed the first symptoms, convulsions with headache, the convulsions being limited to one side of the body. There were as many as fifteen to twenty convulsions in a day, beginning in the arm and extending over the half of the body, associated with inequality of the pupils and later a complete hemiplegia. The possibility of uremia, of cerebral hemorrhage, or of localized tuberculous meningitis was thought of. Among his collection there were four cases of localized meningoencephalitis, with localized hemorrhagic softening which differed from that following obstructions in the arteries.

Dr. LAWRENCE W. FLICK of Philadelphia believed that with a fuller knowledge of what tuberculosis did to the nervous system we might be able to know more definitely the part which tuberculosis played in the development of insanity, mania, and other nervous conditions.

Dr. WILLIAM H. WELSH of Baltimore said we should be able to recognize the diversity of symptoms which occurred in tuberculous meningitis. It had been pictured too often in the text-books as a uniform disease, both anatomically and clinically. It had been his experience in most cases of diffuse cerebral meningitis to have the spinal form with it, a true case of cerebrospinal meningitis.

Dr. DUNNING WILSON of Louisville, Ky., called attention to the difficulties encountered in diagnosing a meningeal tuberculosis when there was a caseation or breaking down in the lungs without the presence of the tubercle bacilli.

Dr. ADOLF MEYER of New York reported the experiences at Mt. Sinai Hospital, in which lumbar puncture was practised and positive bacteriological proof of the tubercle bacilli was made in every single instance.

Dr. VETO of Boston asked Dr. Welsh how he explained the not infrequent appearance of cerebral symptoms late in cases of pulmonary tuberculosis. Did he say that meningitis was the predominant affection?

Dr. Welsh in reply said that it was well known that tuberculous meningitis occurred chiefly in children and infants without any manifestation of pulmonary tuberculosis. In most cases one had to look a long while before localizing any tuberculous foci in the lungs.

Dr. LOWMAN of Cleveland said that many cases of meningitis had been shown not to be tuberculous and were probably a pneumococcic infection from some activity in the lungs.

Dr. McCarthy said that the main point of his paper was that in children it was likely to be a miliary meningitis while in adults it was of the mixed type. He referred to the frequent occurrence of insanity among tuberculous patients. Again, when headaches developed they were important in the diagnosis of tuberculous meningitis, but more often they were due to some eye condition. He agreed that lumbar puncture was a very important method of diagnosing tuberculous meningitis, but he did not believe it was a positive method. If the cerebrospinal fluid was withdrawn into a test tube and held quiet, a reticulum would quickly form which would engage the tubercle bacilli if present, as they gravitated to the bottom.

The Liver in Tuberculosis.—Dr. JOSEPHUS ULLOM of Philadelphia said that tuberculosis of the liver was considered a very rare manifestation by many observers. In 37 cases he had found tubercles 30 times (81 per cent.). Of these 30 livers containing tubercles, 9 were the seat of atypical lesions. All the livers were stained for tubercle bacilli, and the bacilli were found in 6 cases (16 per cent.). Jaundice was present twice in the 37 cases. In 6 of these cases there was tenderness over the liver. Enlargement of the liver was noted in 12, and in 3 of these moderate congestion and atypical tubercles were found, two showed moderate congestion and a marked degree of fatty change associated with typical tubercles, two showed moderate congestion with atypical tubercles, one showed a marked degree of amyloid change associated with tubercles. From a consideration of the clinical and pathological findings in these cases and from a perusal of the reports of other observers, it must be concluded that a clinical diagnosis of hepatic tuberculosis was rarely if ever justified. In conclusion he said that: (1) Tuberculosis of the liver was found in a large percentage of those dying of pulmonary tuberculosis; (2) its clinical recognition was only rarely if ever possible; (3) the infection probably took place by the blood-vessels, the bacilli being carried to the liver by the portal vein or the hepatic artery; (4) passive congestion of the liver was found in nearly every case of pulmonary tuberculosis, while amyloid and fatty changes were found in a relatively small number of cases; (5) from a study of the cases above referred to it was not certain that a fibrosis or cirrhosis of the liver due to the tubercle bacillus did occur.

Dr. ALFRED MEYER of New York asked Dr. Ullom if auscultation of the liver had been practised to see if there were any perihepatic signs.

Dr. H. R. M. LANDIS of Philadelphia said he had abandoned any attempt at making a clinical diagnosis of tuberculosis of the liver, deeming it impossible.

Dr. Ullom said his experience coincided with that of Dr. Landis; a diagnosis of tuberculosis of the liver by clinical means could be made only in rare instances. Dr. Meyer's suggestion was a good one and might be of value in these cases.

The Kidneys in Tuberculosis.—Dr. Joseph Walsh of Philadelphia came to the following conclusions in regard to the kidneys in cases of tuberculosis of the lungs: *Pathological:* (1) A comparison of 100 kidneys from cases of tuberculosis of the lungs, with 26 kidneys from a variety of other conditions, showed apparently nothing outside of tubercles that could be said to be specific to the tuberculosis. (2) Every form of nephritis was found in tuberculosis except hemorrhagic and glomerulonephritis; the most common forms were acute and chronic degenerative. (3) Positive tubercles were found in the kidneys in 55 per cent. of the cases. (4) The most common abnormalities found were fibrous and cellular areas under the investment or throughout the cortex. The former occurred in 69 per cent. of the cases of tuberculosis and 50 per cent. of the nontuberculous cases. (5) The microscopic appearances of the kidneys frequently failed to correspond with the microscopic diagnosis. *Clinical:* (1) Inoculation experiments showed tubercle bacilli in the urine in 82.5 per cent. of the cases. (2) Tubercle bacilli were found in the urine on microscopical examination in 90 per cent. of the cases. (3) Sometimes the bacilli found in urine, even in cases showing tubercles in the kidney, did not affect the guinea pigs. (4) Sometimes bacilli were found in the urine of infected guinea pigs without tubercles being found in the kidneys. (5) Edema was found in 35 per cent. of the cases; it was most frequent in association with acute parenchymatous nephritis. (6) Albumin was found by the heat and acetic acid test in 47 per cent. of the cases; it was found most commonly in connection with amyloid degeneration, though it occurred under all pathological conditions, even cloudy swelling. (7) The detection of casts and pus cells apparently depended on the carefulness of the observer, varying in his studies from 18 to 66 per cent. (8) The heart was commonly normal, both clinically and pathologically; when abnormal, no relation was found between the heart and kidney condition. (9) The nephritis accompanying tuberculosis might be surmised but could not be assured; with the possible exception of amyloid, the kind of nephritis could not be even surmised. (10) The most common clinical symptoms of nephritis in tuberculosis, according to his own personal studies, were hyaline and granular casts and tubercle bacilli in the urine. Less frequent symptoms were pain or ache in the lumbar region, albumin in the urine, and edema. Still other symptoms appeared to be unusual fatigue upon slight exertion, unaccountable dyspnea, and a rapid pulse.

Dr. Lawrence F. Flick of Philadelphia said he had long looked upon the kidney complications of tuberculosis as among the most serious that could occur, and among the most difficult to treat. Unfortunately, we did not often see clinically these cases, yet he was inclined to think that sometimes we got indications which should place us on guard, even though we could not establish the diagnosis. There were two of importance, namely, the rapid pulse and great fatigue. The accentuation of the second sound should give us warning. He had found that the coincidence of rapid pulse and accentuated second sound which he could not control, were forerunners of an acute nephritis from which the patients died.

Dr. E. G. Janeway of New York suggested that the lesions be looked for in the seminal vesicles, the testicle, the bladder, or elsewhere in the genitourinary tract, when the tubercle bacilli were found in the urine without any evidences of tuberculous disease of the kidney.

Dr. Alfred Meyer of New York asked how Dr. Walsh eliminated that disturbing element in the bacteriological examination for the tubercle bacillus, the smegma bacillus.

Dr. Walsh said that Dr. Janeway's point was well taken. In answer to Dr. Meyer's question, he described the method employed by Dr. Flick and himself to distinguish the tubercle bacillus from the smegma bacillus.

Bacteriological Findings in Cases of Tuberculosis Examined at Autopsy.—Drs. J. W. Irwin and M. P. Ravenel of Philadelphia presented this communication. Seventy-five autopsies were made in a routine way and the study upon these were simple, part and parcel of a study of mixed infection in tuberculosis that they were then engaged in. They referred to the experiments of Dr. Prudden showing that rabbits inoculated with the tubercle bacillus never had formed cavities unless they were subsequently inoculated with the streptococcus. They quoted the saying that "the worst thing that could happen to a tuberculous man was to come in contact with a consumptive." Ordinary bacteriological methods were used in their investigations. Of the 75 cases examined only one proved to be sterile throughout. In another case all the cultures were sterile except the one from the liver. In three cases all were sterile except that from the spleen. In one case they obtained streptococci from every organ. In another case they got a culture from every one taken and in pure form from the kidney, liver, and spleen. The streptococcus was found in diploform in 53 out of the 75 cases; the *Staphylococcus pyogenes albus,* 34 times; *Staphylococcus pyogenes aureus,* 33; the pneumococcus, 17; *Bacillus pyocyaneus,* 4; *Bacillus coli communis,* 51; *Bacillus lactis aërogenes,* 3; pseudodiphtheria, 12; sarcinæ, 13; yeast, 15; spirillum, nature undetermined, 1; small diplococcus, 2; unverified bacilli, 5 times; aspergillus, 1; typhoid bacillus in the kidney, 1.

Dr. George Mannheimmer of New York asked Dr. Ravenel if the influenza bacillus was found.

Dr. Ravenel replied that after the most careful examinations the influenza bacilli were not found. The paper, however, referred only to post-mortem findings.

Clinical and Pathological Comparisons of Cavities.—Dr. H. R. M. Landis of Philadelphia read this paper.

Dr. William H. Welsh of Baltimore, Dr. Alfred Meyer of New York, Dr. Miller of New York, Dr. John H. Pryor of Buffalo, Dr. Abbe of Washington discussed the paper.

Tuberculosis of the Placenta.—Dr. Alfred Scott Warthin of Ann Arbor said that only twenty cases of placental tuberculosis had been described so far in the literature, one observer alone reporting half of these, and Dr. Warthin three. Placental tuberculosis he thought to be more common than generally supposed, and it was a fact that tuberculosis could be transmitted through the placenta. The first case he reported was one of ectopic gestation with tuberculosis of the tubes, fetus, and chorionic villi. The second case was met with by him during a study of a series of fifty autopsies while abroad. The third case showed a tuberculosis of the kidney in the mother with acute miliary tuberculosis at about the fourth or fifth month of pregnancy. Abortion took place and the fetus was discharged. Unmistakable evidences of transmission were offered. The placental tissue he believed to be less resistant to tubercle bacilli than formerly supposed.

Dr. William H. Welsh of Baltimore said this, the subject under consideration, was of fundamental importance in the conception of the etiology of tuberculosis. The evidence which was cumulative since the time of Baumgarten's first statement of his views as to the congenital origin of tuberculosis had been along a road every step of which was ridiculed by pathologists. The evidence of the placental transmission of tuberculosis was becoming stronger and stronger. Dr. Welsh was particularly interested in Dr. Warthin's study of the histological details, and in one class he was reminded of the experimental tuberculosis produced in the lungs by injecting a large number of tubercle bacilli directly into the circulation.

He had never been satisfied with Baumgarten's position, that tubercle bacilli caused primarily a growth of cells, contrary to fundamental ideas. He had been anxious to bring evidence that the tubercle bacilli primarily damaged the parts and the proliferation of cells was secondary to that. He thought that certain of the cases Dr. Warthin described as tuberculous should be put to experimental test. He thought tubercle bacilli could be conveyed from the mother to the fetus *in utero*, and more frequently than it had been customary to believe, and he did not think that it was necessary to have any definite and special lesions in the placenta to permit this. The entrance of the bacilli into the fetal circulation might occur so late in fetal life that tuberculosis did not have time to develop. Experimental data seemed to indicate that the fetus was relatively insusceptible. There was support for both of these views. He thought there was considerable evidence that the fetus could have tubercle bacilli without producing tuberculosis, and that they were present in the blood-vessels at the time of birth, and that after birth they might produce lesions. This was an important line for investigation, and further careful study of the placenta in cases of tuberculosis should be encouraged.

Dr. Lawrence F. Flick of Philadelphia said that clinically it was a remarkable fact that children born of tuberculous mothers often did show a strong immunity to tuberculosis at least for months after birth. He had watched the children of tuberculous mothers for years, and many of them were as healthy children as he had ever seen. He asked if it was possible that intrauterine exposure to the tubercle bacilli might not confer immunity upon such children.

Dr. Welsh said that he had had no experience with the matter, but it would be gratifying to believe that children could be vaccinated *in utero*. Here we found living tubercle bacilli more resistant than in adults or individuals after birth, and the conditions would seem to be favorable for the possible production of an active immunity. He hesitated to make any definite statement without fuller knowledge than he possessed at present.

Dr. Laphan of Highlands, N. C., said that the children of tuberculous mothers certainly seemed to possess an immunity, and it was a question how long the immunity lasted. Children of tuberculous mothers very often lived up to a certain age and then under any extra strain they went down very rapidly. He thought that it was generally admitted that tuberculous children developed tuberculosis in a large percentage of cases as they approached the twentieth year.

Dr. Flick said that he had the histories of a number of children of tuberculous mothers in which the mother died within one year after the birth of the child; these children had grown to be unusually well-developed men. He had not had enough such cases to draw conclusions, but he had made enough observations to raise the question of immunity in this regard.

Dr. Edward L. Trudeau of Saranac Lake said that the difficulty with which the tubercle bacilli passed from mother to fetus was more apparent than real; the bacilli might be dormant for days, months, and even years. He had noted in vaccinating cows with no lesions whatever that at the end of one, two, or seven months the bone marrow was affected, but no tubercle bacilli could be found.

Dr. Herbert Maxon King of Liberty, N. Y., said that in 1901 he had read a paper on this subject at the Congress on Tuberculosis in London. It was merely a study of one hundred cases of tuberculosis occurring in children of tuberculous parents. Unfortunately, he had not distinguished between the fathers and the mothers. He had found that the length of life in one hundred cases of children of tuberculous parents after supposed contraction of the disease was 25 per cent. longer than in one hundred cases of children of nontuberculous parents. This matter had not been sufficiently studied to admit of definite conclusions.

Dr. Lowman of Cleveland said that he had made some observations in Cleveland since last November on tuberculous children. He had 350 children of tuberculous families come to the clinic, and 10 per cent. were found to have tuberculosis, 10 per cent. more were strongly suspicious. If the children in families where there was tuberculosis were examined with greater care it would be found that there was not so much immunity as suggested. These children, as a rule, looked well and were larger than other children of the same age, yet they had well-marked areas of infection. He seriously doubted if there was such immunity conferred as had been suggested.

Dr. Flick said that the statistics confirmed what he had said, namely, that they were so immune that they would not give evidence of the disease, and that they had more resisting power than children born of nontuberculous parents. It remained to be seen whether these children could throw off all evidences of the disease and grow to be strong and healthy men and women.

Dr. Warthin, in reply to Dr. Welsh, said that there was no better demonstration of the primary effects of the tubercle bacilli in the way of necrosis than was found in the placenta.

Common Errors in the Technique of Examining Sputum for Tubercle Bacilli.—Dr. Charles L. Minor of Asheville read this paper.

Dr. Wm. Kraus of Memphis discussed it.

Concerning Bacillus X.—Dr. S. J. Maher of New Haven read this paper, and in conclusion called attention to these easily demonstrable facts: (1) Normal X or *Bacillus mycoides* III, an organism that was obtainable often in pure culture from vaccine, from green grass, from the needles of the pine and the leaves of the balsam firs and hemlocks in the depths of the forests, this bacillus that in its ordinary form might be, with impunity, injected alive into man or brute could, by subjecting it for prolonged periods to the inhibiting effect of its own secretions, and to the nuclear or spore stimulation of weak salt solution, be forced to take on new forms and properties, and these new forms, by careful cultivation, could be made to persist. (2) In one of these new forms this organism became largely acid-fast, could cause the production of caseating masses in injected rabbits. (3) From these caseous nodes, in which were to be found on smears either no bacteria or only acid-fast rods or cocci, might be grown the mixture of acid-fast and non-acid-fast rods and cocci that were injected into the animal weeks before. (4) Cultures in sugar bouillon and physiological salt solution of this partly acid-fast and partly non-acid-fast organism would, on injection into other rabbits, cause the development of caseous nodes in the second series of animals.

Dr. George M. Sternberg, Ex-Surgeon General, U. S. A., thought that these results would have to be controlled before they were accepted by bacteriologists to-day.

Dr. Oertel of Augusta, Ga., reported seventy-three cases in which he had used cultures of the *Bacillus X*, sixty-three of them being crazy negroes in the State institution, and in all stages of tuberculosis except the first. He had nine apparent cures and three were well to-day. One of the institution patients, a glandular case with discharging sinuses, who was an epileptic and a fool, after four injections about three weeks apart in the neighborhood of the enlarged glands, was apparently well to-day, all enlargement of the glands having disappeared.

Serum Diagnosis of Tuberculosis.—Drs. Hugh M. Kinghorn and David C. Twichell, M.D., of Saranac Lake read this paper. The work was done in the Saranac Laboratory under the direction of Dr. E. L. Trudeau. The method used was that of Arloing and Courmont, and the A. homogeneous culture of these French investigators was employed. All the tests were made according to the directions of Paul Courmont. The culture was grown in

a bouillon consisting of peptone, 20 parts; sodium chloride, 10; glycerin, 40; water, 1,000. This was neutralized with normal soda solution. This was Courmont's formula.

Clean, fresh serum was used for the tests. When agglutination took place at 1 to 5 the reaction was considered positive. The tests were made at room temperature, and the time limit given to them was five hours—not more. Agglutination was observed by the naked eye. Results were considered positive only in those tubes which showed well-marked flocculi easily visible to the naked eye, with subsequent sedimentation and clearing. The total number of cases tested was 247. Of these 70 were persons in apparently good health, 155 were patients with pulmonary tuberculosis, 22 were patients with doubtful tuberculosis or with other diseases. Of the 70 healthy persons, 59 reacted, 84.28 per cent.; 11 failed to react, 15.72 per cent. Of the 155 patients with pulmonary tuberculosis 135 reacted, 87.09 per cent. 20 failed to react, 12.91 per cent. Of the 22 patients with suspicious signs of tuberculosis and with other diseases, 18 reacted, 4 failed to react. The 70 healthy persons whose serums were tested were in apparently sound health. Most of them belonged to the better classes of society. Some of them had been exposed to patients who were suffering with pulmonary tuberculosis. The average strength of agglutination in these cases was 1 to 13.67. The 155 patients with pulmonary tuberculosis differed widely as regards the extent and gravity of their disease. They included latent or healed cases, tuberculin test cases, incipient, advanced, and far-advanced cases. Of 17 cases which reacted to the tuberculin test all reacted to the serum test. Of 38 incipient cases 36 reacted, 94.73 per cent.; 2 failed, 5.27 per cent. Of 95 advanced and far-advanced cases 78 reacted, 82.10 per cent.; 17 failed, 17.90 per cent. Of 5 latent or healed cases, 4 reacted, 1 failed to react. In comparing their work with that of Paul Courmont it was to be noted that the tests were all made according to Courmont's directions, and his A. homogeneous culture was used throughout. In clinical cases of tuberculosis Courmont obtained 87.9 per cent. of positive, 12.1 per cent. of negative reactions; Kinghorn and Twichell obtained 87.09 per cent. of positive, 12.91 per cent. of negative reactions. In persons in good health Courmont obtained 26.8 per cent. of positive, 73.2 per cent. of negative reactions; Kinghorn and Twichell obtained 84.28 per cent. of positive, 15.72 per cent. of negative reactions.

It was the opinion of the author of the paper that there was little, if any, difference between the agglutinating power of healthy and tuberculous serums, namely, 84.28 per cent. for healthy and 87.09 per cent. for tuberculous serums. The average agglutination was also practically the same, namely, 14.82 for tuberculous, 13.67 for healthy persons. From their investigations Drs. Kinghorn and Twichell concluded that the serum diagnosis of tuberculosis as used by Arloing and Courmont was not a specific sign of the presence of clinical tuberculosis, since healthy and tuberculous serums had practically the same agglutinating property. They concluded that the serum diagnosis of tuberculosis, especially for the early diagnosis of tuberculosis, was of no value.

Dr. Karl von Ruck of Asheville said that all the cases in his institution had been carefully examined during the past year, and while no results had been gained, he had found a large percentage that failed to react to the agglutination test, although there were distinct evidences of tubercle bacilli in the sputum.

Dr. S. A. Knopf of New York said that Drs. Park and Lambert had tried the agglutination test at Bellevue Hospital and came to the conclusion that it was practically valueless in tuberculosis.

Dr. William H. Park of New York stated that those tests were roughly made, and their results should be substantiated by more careful work.

Technique of the Tuberculo-Opsonic Test.—Drs. Kinghorn and Twichell also presented this paper. They were at present engaged investigating the work of A. E. Wright of London, England, especially in connection with tuberculosis. According to Professor Wright, the phagocytic effect obtained when bacteria were introduced into the blood was dependent upon an action exerted by the blood fluids directly upon the microorganisms. He spoke of this action, which prepared the microorganisms for phagocytosis, as an opsonic action (Latin—*opsono*, I cook, I prepare pabulum for). It was due to the presence in the blood fluids of substances which modified tubercle bacilli in a manner which rendered them an easy prey for the phagocytes. The following observations had been made by Professor Wright and Captain S. R. Douglas: (1) Opsonins are contained in the blood fluids—serum or plasma. (2) They lose their power when heated to from 60° to 65° C. for ten to fifteen minutes. (3) They exercise their influence by effecting a modification in the bacilli, and not by exerting a direct stimulating effect upon the phagocytes. The object of the present paper was to discuss the technique of the method used in estimating the opsonic power in the blood of tuberculous patients, and also of those undergoing tuberculin treatment. The method employed by Professor Wright was as follows: Equal quantities of the patient's serum, an emulsion of tubercle bacilli, and white blood corpuscles (washed in ½ per cent. sodium citrate in physiological salt solution) were mixed in a capillary pipette and incubated at 37° C. for twenty minutes, after which blood films were made of the mixture and stained for tubercle bacilli. The average number of tubercle bacilli ingested by each polymorphonuclear white corpuscle was calculated, and the figure thus obtained was called the phagocytic index. The opsonic index was the result obtained by dividing the number of bacteria taken up per leucocyte in the presence of any given serum by the number taken up per leucocyte in the presence of the serum of a normal individual, which latter was regarded as unity. For example, the number of tubercle bacilli per leucocyte in the presence of a given serum equals 3; tubercle bacilli per leucocyte in the presence of a healthy serum equals 2; then 2:3::1: opsonic index = 1.5. The difficulties which Drs. Kinghorn and Twichell experienced in making the tests were considerable, and they gave in detail the various steps as to their methods of obtaining the washed leucocytes; the emulsions of tubercle bacilli for phagocytosis; the serums for the tests; the method of mixing and incubating the washed leucocytes, the serum, and the emulsion of tubercle bacilli; the method of preparing slides, and the method of hardening and staining the slides. They emphasized the fact that they considered it necessary to count from one hundred to two hundred polymorphonuclear cells in order to make an accurate estimate.

They intended to give at a later date the result of their work with the opsonic test on patients undergoing tuberculin treatment. This investigation was being carried out in the Saranac Laboratory under the direction of Dr. E. L. Trudeau.

Dr. Nathaniel Bowditch Potter of New York and Dr. E. R. Baldwin of Saranac Lake discussed this paper.

Studies on Immunity in Tuberculosis: Experiments with Lymph Glands and Bone-Marrow Extracts of Immunized Animals.—Drs. E. R. Baldwin and J. Woods Price of Saranac Lake presented this communication. The paper consisted of a report of experiments still in progress with the tissues of immunized calves used for the protection of guinea pigs against experimental tuberculosis. The leucocytes were obtained from the uncoagulated blood of an immunized cow, which was removed at different times during or following a tuberculin reaction. The lymph nodes and bone marrow were also taken from a calf killed at the height of a tuberculin reaction. Thus far no evidence of any protective influence had been obtained which was transferable to guinea pigs.

SECTION ON DISEASES OF CHILDREN.

Third Day—Thursday, June 7.

Acute Nonsuppurative Encephalitis in Children.—Dr. ISAAC A. ABT of Chicago presented this paper, saying that attention was first called to this class of cases by Strümpell in 1884. This publication had aroused much interest, and subsequent investigations seemed to show that Strümpell was not entirely correct in his assumption that cerebral palsy in children was due to a single process. During the last few years, however, the many contributions made to the subject had left no doubt that Strümpell's position was essentially correct that acute encephalitis was responsible for a proportion of the cases of hemiplegia in young life. The author, from a large number of histories of the disease, was impressed with the fact that there were several clinical types of the disease. Two cases recently under his observation constituted the subject of the clinical report. The eitology of acute nonsuppurative encephalitis, Dr. Abt said, might be briefly summed up in the words, infection and intoxication. Acute alcoholism possibly played a rôle in adults and older children. In one of Wernicke's cases poisoning with sulphuric acid was suspected. In other cases nicotine had been thought of as a factor. The infective source, however, was considered the most frequent of all in the encephalitis of children. Any portion of the brain might be affected, though the cortex or encephalitis superior (Strümpell's variety), the basal ganglia and the region of the medulla, or encephalitis inferior (Wernicke's variety) were selected areas. The symptomatology was considered at some length. The terminations of the cases were summarized as follows: A small proportion of the patients do not survive. If the encephalitis occurs during acute infectious disease death may result from cerebral conditions or from the original disease. Some cases improve within a few days. There is always a liability to hemiparesis of the side of the body or to epilepsy. The majority of cases with initial flaccidity give rise later to the spastic type of hemiplegia. The diagnosis during the acute stages was nearly always difficult; there was suggested an acute infectious disease on the one hand or a meningitis on the other. The disease might be confused with a tuberculous meningitis. Spinal puncture in these cases was of little assistance.

Dr. H. LOWENBURG of Philadelphia had seen a case of complete hemiplegia in a child in which convulsions occurred on the second day during an eruption of measles and lasting for 48 hours. After the convulsions the child had complete hemiplegia of the left side. The case had been looked upon as a hemorrhage into the cortex above the decussation of the seventh nerve. He inquired whether in Dr. Abt's cases the reactions of degeneration were taken.

Types of Congenital Symbol Amblyopia.—Dr. J. HERBERT CLAIBORNE of New York City in this paper said that W. Pringle Morgan of England was the first to point out the fact that in addition to the word-blindness which is the result of acquired cerebral lesion, there is a word-blindness congenital in nature which he has suggested as due to defective development of the word memory centers of the cerebral cortex. Dr. Claiborne reviewed the literature on this subject and said that this literature in America was confined to the papers of Dr. A. Chapringer of New York and himself, which were read before the New York Academy of Medicine, February 19, 1906. Dr. Claiborne detailed the history of two cases of so-called congenital word-blindness in two boys of ten and nine years respectively. He thought word-blindness was an incorrect expression for these cases, and suggested "word amblyopia" instead, since blindness did not exist, but rather imperfect vision, inasmuch as both boys were able to recognize and read a few words constantly practised. When such patients were right-handed Dr. Claiborne pointed out the great probability of the lesion being on the left side of the brain and in the neighborhood of the angular gyrus. Reference was also made to imperfect word-deafness, and he suggested the expression "word-amblykusis" as descriptive. Dr. Claiborne also referred to the fact that many people were unable to learn mathematics, and he suggested the thought that this deficiency was parallel with word-amblyopia and word-amblykusis. He pointed out that many persons who could not reason in symbolic mathematics were quite capable of solving the same problems when they were reduced to words or involved material things. He drew the simile of the theoretical man and the practical man, and suggested the term "figure-amblyopia" for this form of mental defect. He also referred to the imperfect musical appreciation of some persons, and classed this under two heads: the written symbol musical defect and the auditory symbol defect. For the imperfect musical sense he suggested the term "amblymusia" as opposed to amusia. He referred to the fact that at present no post-mortem corroboration of these assumed congenital lesions was on record. When these various defects were met in schools Dr. Claiborne said they should be carefully differentiated and properly grouped, and the children should be instructed. The basis of the instruction should be repetition coupled with patience. He thought it reasonable to teach such children to become left-handed, in order that the speech, symbol and sound centers on the right side of the brain might be cultivated to the exclusion of those on the left, or as supplementary to them.

Accurate Modification of Milk, Simple and Practicable.—Dr. DANIEL R. BROWN of Salem, Mass., demonstrated the mathematical principles on which the calculation of percentage mixtures depends. Working formulas were given, and the simplicity was shown of the percentage modifications, both for the preparation and for the use of modified milk under the immediate direction of the physician.

Simplicity in Infant Feeding.—Dr. CHARLES W. TOWNSEND of Boston said that the average physician was generally so discouraged by the mathematics of present-day papers on infant feeding that he formed an exaggerated idea of the difficulties or rejected all theories in disgust and resorted to the printed directions of advertising food manufacturers. Too great manipulation of the milk, he asserted, interfered with its physical and vital characteristics. On that account he felt that the use of centrifugal cream, of fat-free milk, and the employment of Pasteurization or sterilization were all undesirable. Gravity cream he considered should be the basis of all modifications, and this could be obtained by the simple method of pouring off the top milk from the milk bottle. The richness of the top milk, he suggested, could be varied by pouring off more or less as required. Instead of using water as a diluent he suggested the advantage of cereal water, which could be used even in the youngest infant. In beginning to feed an infant whether newborn or an older one that had suffered from improper feeding, the safest rule, in his opinion, was to begin with a mixture weak in all its ingredients, and by slow degrees gradually to increase the strength.

Certified Milk in Small Cities.—Dr. C. W. M. BROWN of Elmira presented this paper, saying that in spite of the increase of knowledge concerning the production and care of milk the fact remained that ordinary milk, while of almost universal use, was the most uncleanly article of food on the table. That commercially Pasteurized milk might be more unsafe than ordinary milk he said was abundantly proven by the investigations of Pennington and McClintock of Philadelphia. Although anticipating that hospitals would be furnished with good milk, yet Edsall found many

of them in Philadelphia served with milk of "shocking quality," some of it containing millions of bacteria to the cubic centimeter. Mention was made of the first Medical Milk Commission, that of Essex County, N. J., formed and pushed to success by Dr. Henry L. Coit of Newark. This Commission had issued its first certificate in 1893. Since that time thirteen other Commissions had been started; all, however, with the exception of the Commission of the Elmira Academy of Medicine, were in the cities of the first and second class. Because of the successful accomplishment of the work of this Commission in a small city and at the suggestion of an ex-president of the section the account of the work was given with the hope that others of the smaller cities might be similarly stimulated. The efforts of the Milk Commission of the Elmira Academy of Medicine resulted in finding a woman who was willing to take up the work and who already had a general knowledge of the benefits of clean milk and the requirements to produce it. She built a new barn, had her herd tested for tuberculosis, the Commission selected its experts, and the first certificate was issued April 15, 1903. A standard of a 10,000 bacterial count was established and the other usual conditions imposed. The milk was cooled and bottled within a few minutes after it was drawn, put in the crate, the top of which was filled with cracked ice, and the night and morning milk was delivered to the consumer not more than 19 hours from the time the oldest of it was drawn the night before. This had been accomplished by simply using the means at hand, and what had been done in Elmira it was thought by the author could be done inside the next twelve months in a score of the other cities of the size of Elmira which were now not supplied with clean milk. He pointed out two great hindrances to successful progress of right infant feeding in cities: (1) The difficulty of securing fresh, clean milk, resulting in an increased sale of artificial foods; (2) the lack of knowledge among physicians of the proper modification or adaptation of cow's milk to the infant. The responsibility for the first he placed upon the physicians in each town; that for the second, upon the teachers of pediatrics in medical colleges and postgraduate schools.

Why Percentage Feeding Fails; a Plea for Its More Frequent Adoption by the General Practitioner.—Dr. H. Lowenburg of Philadelphia presented this paper, in which he said that pediatrists were agreed that percentage feeding was the best way to rear children artificially, however they might differ as to methods. He showed that causes of failure lay in the bewildering multiplicity of methods of modification and in the fact that proposed methods were not intelligently applied. Written formulæ need not represent the actual percentages. Physicians and parents he thought expected gain in weight too soon. The physical and biological differences between cow's milk and human milk were not sufficiently recognized; neither did physicians recognize the variety of indigestions, nor think in percentages. Mothers and nurses should be educated in pediatric hygiene, and in this there was a lack of professional supervision. Physicians and mothers, he stated, were deluded by patent foods.

Pleuritic Exudate in Children.—Dr. Melinda K. Germann of Quincy, Ill., in this paper stated that pleuritic exudate, either serous or purulent, was common in infancy and childhood, more particularly in the latter. By bacteriological examinations the pleuritic exudates were divided into three large groups; the first caused by the tubercle bacillus; the second by the pneumococcus; the third by the streptococcus. The physical signs of fluid in the pleural cavity in children differed somewhat from those in the adult. With failure of expectant treatment to favor resorption of the exudate, aspiration was advised. In the differentiation of empyema from acute unresolved pneumonia, serofibrinous exudates, chronic adhesive pleurisy, and atelectasis, aspiration alone would aid. In treatment, thoracotomy, with or without resection of portions of one or more ribs, was preferred to aspiration.

Tetanus Neonatorum.—Drs. J. M. Anders and A. C. Morgan, of Philadelphia, presented this paper, showing their studies of 1,276 cases collected from the literature from 1850 to 1905, and of 31 original cases reported by themselves, a total of 1,307 cases. The study was limited to the occurrence of the disease in the newborn babe, with infection through the umbilicus. All observers were a unit in declaring that the most prolific cause of the occurrence and mortality of the disease was unclean midwifery. Suggestions as to prophylaxis were submitted as follows: The education of persons directly or indirectly concerned with the care of confinement cases should be insisted upon, especially as to the necessity for rigid, aseptic, hygienic care of the umbilical stump and its treatment along the same strict lines as any other surgical wound. To this end a law in every State, requiring registration of midwives, should be enacted. Medical colleges should teach this phase of the matter with greater earnestness than is now being done. Likewise, the subject of the tetanus bacillus should be fully presented. State Boards of Health should issue circulars of information for the guidance and direction of midwives and others who attend these cases. Philanthropic societies and institutions should also take up the question and cause a widespread knowledge of the simple measures necessary for the prevention of this disease.

The Rheumatism of Childhood.—Dr. J. Ross Snyder of Birmingham, Ala., said the tendency was to multiply the number of diseased conditions having relationship with rheumatism. In connection with the rheumatism of adults confusion was being cleared away by satisfactory classifications of acute and chronic joint affections. Child types, however, had been left out of consideration. Clinical evidence, he said, now pointed to its infectious origin. The idea of endocarditis must not be too closely associated with rheumatism, and much could be said against the close association of chorea with rheumatism. The author asserted that unless it was believed that rheumatism was no more or less than a general streptococcus infection, many cases of arthritis and endocarditis following tonsillitis were no more rheumatic in nature than the cases of acute pyemic arthritis of infants. The author suggested that erythema nodosum might also be proven to be a streptococcus infection, the portal of entry being the tonsils. The opinion was expressed in conclusion that one by one many of the so-called manifestations of rheumatism would be taken from the list of symptoms of that disease until rheumatism would mean something or nothing.

The Clinical Aspects of Rheumatic Fever in Childhood, and their Significance in the Question of Specific Etiology.—Dr. Charles Hunter Dunn of Boston said there was a lack of definite knowledge of the etiology of the disease termed rheumatic fever. Among those believing that rheumatic fever was an infectious process, two views were held as to its etiology: (1) The bacteriological view that the disease is a specific infection, due to a specific microorganism. (2) The clinical view that the disease is not due to a specific infection, but that it is a particular reaction of the body to a variety of organisms. The author believed that those who regard rheumatic fever as a specific reaction of the tissues to a variety of infections might prove to be right, but that at present further evidence was needed in support of their position. On the other hand, until there was some method of recognizing the *Micrococcus rheumaticus* as a specific entity other than by the results of animal inoculation, it could not be accepted as the absolutely proven cause of the disease. He thought it could, however, for the present be granted the position of a probable specific cause. The author considered the definiteness of the clinical picture alone a sufficient justification for regarding rheumatic fever as a definite entity, and most probably a specific infection to be placed in the same category as scarlet fever and measles. Whether the specific cause had been discovered was another matter.

(*To be continued.*)

MEDICAL SOCIETY OF THE COUNTY OF KINGS.

Regular Meeting, Held May 15, 1906.

DR. WILLIAM F. CAMPBELL IN THE CHAIR.

Recent Experimental Work Bearing on the Etiology of Cancer.—Dr. HARVEY R. GAYLORD, Director of the New York State Cancer Research Laboratory, Buffalo, N. Y., read this paper. He said that five years ago he had addressed the Kings County Society on this subject, and that the intervening time had been fruitful years of research. The parasitic theory of cancer had not lost in prestige, and he believed that the next five years would behold a complete solution of the cancer problem. The recent acquisition of knowledge on this subject had been due to newer experimental methods. On the former occasion he had spoken of the inclusions of the cancer cells, similar to the inclusions in smallpox. At that time there had not been nearly as much evidence as now of the infective nature of cancer, nor had it been necessary to assume that cancer is an infectious process. The speaker had also pointed out a relation between cancer and the acute exanthemata. In this short time a change had taken place. The observation of a possible infective nature of cancer had dated back for many years. As far back as 1875 Novinsky had transplanted a round-celled sarcoma into dogs, one or two of which recovered spontaneously. In 1883 Wehr had transplanted a similar tumor. Following him, Hanah had transplanted epitheliomas in rats. Ten years ago Moreau had transplanted for over two years portions of a carcinoma from mouse to mouse. He had been the first one to show that heredity has very little to do with susceptibility. Leo Loeb in this country had been a pioneer in this work. He worked in Buffalo in 1903, before Jensen's time. Besides the latter were mentioned Bashford of London, and Morel in France. Ehrlich discovered 164 white mice with tumors. Loeb had reported one case of spontaneous cure. The speaker himself had seen eight such cases. Nearly 62 mouse tumors had been known to the authorities of the Pasteur Institute. In order to collect as many mouse tumors as possible, the Buffalo Laboratory had offered a reward for each case of mouse tumor that a dealer might bring in. If a dealer would bring in one he would soon bring in another. One dealer in Springfield had brought in three. These facts indicated the endemic occurrence of sarcoma in the various breeding cages of the dealers. Borel had an interesting experience in Paris: A woman had bred mice in one cage, and twenty of them developed cancer of the breast. In another cage five similar cases developed. Of 180 mice that developed tumors, all had been elderly females with one exception. All the cases that Gaylord had had and all those of Bashford had occurred in females. His explanation of this peculiar occurrence was that the females had been caged for breeding purposes, that several of them had been nursing young, and that the promiscuous suckling of the latter had caused the spread of the cancerous infection. The communicability of cancer was a vital question, concerning which health boards, citizens, and family physicians especially could not fail to be profoundly interested. Five out of twelve of Borel's mice had developed the tumors. In 1901 Dr. Leo Loeb received a rat with sarcoma of the thyroid, which he succeeded in transplanting. In 1902 a second rat appeared in the same cage with an identical tumor. In 1903 a third rat appeared in the same cage with a similar tumor. All three cases had been the offspring of a group of rats that had been brought into the cages for breeding purposes. These cases had been published as a proof of the theory of the endemicity of cancer, but this assertion had to be qualified by the statement that possibly heredity had been the factor at work. In the spring of 1904 a group of rats had been used in experiments on trypanosomiasis. In the summer of that year, of four of the rats left over, one had been found with a large fibrosarcoma of the subcutaneous tissue of the breast, and of a slowly growing nature. Into that cage had been afterwards introduced eight normal rats taken from outside. In 1905 four of these had died, and two of these had been found with a large fibrosarcomata of the breast, in one, and a typical sarcoma of the thyroid in the other. These facts indicated strongly the infective nature of cancer, the infection having lingered in the cage. The existence of the so-called cancer-houses was in perfect agreement with these observations. The mice that had been experimented upon had been carefully controlled; they had been carefully tended and fed on the same food. One objection to the argument of the infective nature of cancer as derived from the observation of cancer-houses, had been that in most instances the secondary cases of cancer appeared many years after the primary ones. But the observations on the rat showed that the intervals between the appearance in the same cage of rats with tumors amounted in most instances to one-third of the lifetime of the rat. Moreover, the experience in some diseases, such as syphilis, indicated that active symptoms, as the tertiary ones in the latter disease, appeared sometimes as late as fifty and sixty years after the primary infection. Thus the interval of freedom from infectivity in a house or a cage was no criterion upon which to base an argument.

The speaker next discussed the subject from the experimental and histological standpoint. He said that the conditions which governed the transplantation of tumors, were not conditions which governed the primary formation of these growths. Most of the mice showing the latter had been old females. Some mice could never be inoculated. Besides, the proportion of mice that could be inoculated depended upon the nature and source of the tumor. The Jensen tumor gave 40 per cent. of inoculations. A tumor derived from a Brooklyn mouse gave 5 per cent. of inoculations at first, then hovered between 5 and 10 per cent. for three or four generations, and the inoculability increased rapidly, until two months ago the tumor produced 100 per cent. of successful inoculations. Moreover, the intensity of growth of the inoculated tumors had increased apace until in the latest tumors the growth was so rapid as to produce in eight days a mass the size of the rat itself. One marveled at the immense reproductive power of these tumors. In one year a tumor produced sixty generations of transplantations. Ehrlich had estimated that a tumor could produce in one year an amount of cancerous material equal to ten grams raised to the sixtieth power, which was equivalent to a cube whose sides were 1,000,000,000 kilometers long. As regards pathological investigation of tumors, it did not bring one anywhere except to a blind wall. What had been shown by the continued transplantation of a growth? The cancer began with a single cell. Something happened to this cell, changing it into one which no longer proliferated normally. It acquired this one undoubted factor of all new growths, namely, that of unlimited proliferation, the cells being unaffected by senility. It must have been affected by a stimulus that normal cells did not possess. The single cell might in the course of one year become billions of cells, each with an activity many times greater than that of the original cell. The speaker asked what kind of agent could thus, when many times diluted, become more and more virulent? It could not be a chemical agent, for this could not reproduce itself. It could not be a toxic agent, for this would be counteracted and thus reduced by antitoxic substances produced in opposition to it. The stimulus had to be a living one. The power of reproduction was the dividing line between the living and the purely chemical. The stimulating agent had to be definite; how definite was the next question to decide. It had been conceded that at the margin of beginning epitheliomas, the epithelial cell became the cancer cell. Prof. Orth had actually demonstrated this. It had been discovered within the last two years that 22 per cent. of the mice with the Jensen tumor recovered spontaneously.

Spontaneous cures had occurred in the case of large and small tumors. Eighty per cent. of the cures occurred in the earliest cases and the prospect of cure diminished as the age of the growth increased. The prospect of cure was thus inversely proportional to the size and age of the tumor. The mice that had recovered could not be reinoculated. This was a fundamental fact, essential for the possible serum cure of cancer. When a histological study of the retrogressing tumors was made there was found no necrosis of cells; the atrophy was merely secondary. Karyokinetic figures had been found until the last. There had been no necrosis, and no cytolysis. The Jensen tumor could be made to retrograde with the *x*-ray. It was important to determine how the *x*-ray worked. A wart could be removed by means of the *x*-ray without necrosis or inflammation of the skin. The upper layer of the wart was desquamated, but the cells of the deeper layer resumed their normal function and proliferated to form new skin. The same process occurred in the treatment of epitheliomas in the mouse by means of the *x*-ray. One saw at the margin of retrogressing tumors the same picture, whether the tumor had been acted upon by serum or by the *x*-rays, and the picture was seen as in the case of the retrogression of misplaced epithelium. It was evident that in all these cases the same agent had acted in the same way. The action began at the margin and proceeded inward. Dr. Clews of Buffalo had shown that the blood of an immune mouse could rob the cancer epithelium of its power of proliferation. This research had a definite significance in its bearing on the problem of the serum-therapy of cancer. Last year, Ehrlich had succeeded three times, by means of transplantation experiments, in transforming mouse carcinomas into sarcomas. Ehrlich had also found that an immunity in the mouse produced against carcinoma acted also against sarcoma. The question, therefore, concerned itself not with a definite cytolytic process. It was possible by increasing the temperature to increase the virulence of the new growth. A further rise of temperature through 5° would reduce the virulence. This was exactly the same experience as with bacteria. Normal epithelium did not act in this way. Heat, if carried sufficiently high, would cause coagulation necrosis of the cells. In the experiments on immunity one had to take account of a variable factor, virulence, on the one hand, and a variable factor, immunity, on the other. It was found that inserting a needle into a small tumor would cause its retrogression. This effect was of the same nature as that which was produced by adding blood serum to cancer cells in the test tube. The needle set free a certain amount of serum into the cancer, and this serum exercised that power which conferred on the animal natural immunity. The success reported by Beard of Edinburgh as following the injection of trypsin into cancerous growths really depended upon this setting free of serum, and was identical with that which would follow the injection of any other inert substance. Squeezing the tumor or causing it to bleed would have the same effect. This experience was analogous to that of surgeons. The success following excision of a growth was not always due to total ablation of the cancer cells. In some cases even thorough removal of all infected parts did not suffice to prevent a recurrence, while in other cases a partial removal of the growth was sufficient to effect a cure. How was this discrepancy to be explained? One was obliged to recognize a condition of equilibrium between infection and immunity. There was a point in which the equilibrium was in favor of the tumor, and *vice versa*. In the early stages a little interference such as puncture, incision, or squeezing served to turn the equilibrium in favor of the immunity, while in the latter stages it served to make the tumor grow worse. The results of surgical intervention seemed to be related to the amount of blood that was lost. The operations in which the loss of blood was least were the most successful. This conserved the natural immunity of the patient.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending July 28, 1906.

	Cases	Deaths
Tuberculosis Pulmonalis	393	147
Diphtheria	166	24
Measles	213	21
Scarlet Fever	54	1
Smallpox	—	—
Varicella	18	—
Typhoid Fever	98	10
Whooping Cough	43	16
Cerebrospinal Meningitis	12	12
Malarial Fever	.....	.....
Totals	997	231

Methodical Protection Against Paludism.—P. Desfosses discusses this subject in a very practical manner, presenting at the same time cuts which illustrate his descriptions. He declares that the methodical protection of dwellings by the means of metal netting offers a practical and sure defense against attacks of malaria. It has been determined that now under complete protection not one case of the disease occurs in malarial regions in which the proportion of individuals attacked by malaria formerly varied from 57 to 60 per cent. With almost complete protection the proportion is 1 38-100 per cent. Protection does not hinder the view, nor does it spoil the ventilation of the apartments. It protects the inhabitants against flies as well as mosquitoes.—*La Presse Médicale.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon General, Public Health and Marine Hospital Service for the week ending July 28, 1906.

DOES THE DRINKING OF WATER GIVE TYPHOID FEVER?

BY R. G. ECCLES, M.D.,

BROOKLYN, N. Y.

THAT the development of typhoid fever is connected with the use of infected water there is no reasonable room to doubt. The facts substantiate this hypothesis too firmly for it to be likely ever to be seriously shaken. That typhoid fever results from the *drinking* of infected water is quite a different proposition, and one that there are many reasons for doubting. The general belief among medical men, at present, is that the drinking of polluted water gives this disease. Since the polluted water does, somehow, give the disease, the assumption has been made that it results from the drinking of such water. There is no recognition of the fact that other explanations are possible and may be better. A diligent search of the literature of this disease has failed to reveal any evidence whatever that the drinking of water ever caused a single case, that the drinking of water could possibly start a case, or that there are any indications pointing to the possibility that spring, well, river, or hydrant water can reasonably be charged with having probably started any particular case. The belief, though almost universal among medical men, that typhoid fever is started by the drinking of water, appears never to have met with the slightest support from any facts. So far as can be discovered from the literature it is a pure assumption, unsubstantiated by either experiment or experience. It seems to have been taken for granted that, since the water and the disease are related to each other, the relation must be through the particular water which we drink; this, too, in defiance of known facts that stand in opposition to so gratuitous an assumption.

Prior to the Spanish-American War the belief was universal that if our soldiers could be induced, persuaded, or compelled to refrain from drinking water that had not been boiled they would remain immune, or nearly so, to typhoid fever. The Surgeon-General sent out an order for all the men to boil the water used for drinking. Probably many of them disobeyed this order, but a large proportion of them obeyed it. What was the result? Was there any diminution in the proportion of diarrheal diseases? So far as we can learn there was not. Past records were repeated. More soldiers died of diarrheal diseases than of bullets. So numerous were the cases and so alarming was the number of those who died from typhoid that a special commission was appointed to inquire into the cause of so terrible a mortality. The believers in the theory that the drinking of bad water was the sole or chief cause of this disease were shocked at the failure of their sovereign remedy; but their gospel of salvation was scotched, not killed. Popular theories die hard; their destruction can only be accomplished piecemeal. The British soldiers during the South African War had a like experience, and, although greater strictness was practised with them than with our men, in the matter of using only sterile water when water direct from uninhabited mountains was unobtainable, the results were the same. The Japanese army had no such experience, and while their water was also boiled there is no reason for believing that the boiling of the same did them any more good than did the boiling of that consumed by the British and Americans.

About thirty-five years ago Prof. Joseph Leidy of Philadelphia said that he believed that flies were responsible for many cases of disease, and advised hospital surgeons to keep these pests out of the wards. He had examined a number of flies, microscopically, which he found feeding on fungi, and discovered that a fluid which exuded from their proboscides, and also the contents of their stomachs, were swarming with spores.[1] Nearly forty years ago Hoffman demonstrated the presence of tubercle bacilli in the bodies of flies captured in a room occupied by a consumptive. The excreta of the flies were full of bacilli.[2] Nuttall showed that the common house fly, when fed on plague bacilli, were found to contain them forty-eight hours after the meal.[3] Hart declares that there are well-authenticated cases of flies having carried Asiatic cholera, and that Haffkine found cholera spirilla in milk exposed in new vessels to flies.[4] Howard declares that it has been experimentally found "that every footprint of an infected fly on sterile culture media was followed by a discrete colony of the germ."[5] As most of our food constitutes an excellent culture media for germs, and as flies have been demonstrated to carry disease germs to food, it is an easy step to ascertain where lies the common source of infection from not only typhoid fever, but many other diseases. The fact that flies go through human excreta, garbage, slops, sputa, and decomposing matter in one minute and then, at the next, wading over our food, is certainly not a very pleasant thought to contemplate. In the Report of the Army Medical Commission that studied the cause of the typhoid epidemic among our soldiers we are told that flies "swarmed over fecal matter in the latrines. They visited and fed on food prepared for the soldiers in the mess tents. In some instances, when lime had been recently sprinkled over the contents of latrines, flies, *with their feet whitened with lime,* were seen walking over the food."[5] Dr. Tooth states that during the Boer War in South Africa the soldiers found the flies to be a veritable plague, and says: "They were all over our food, and the roofs of our tents were at times black with them."[6] In the American Report we are told that "officers, whose tents were protected by means of screens, suffered less proportionately from typhoid fever than those whose tents were not so protected."[5] Dr. W. G. Thompson points out that, in 1898, "fly infection was much more disastrous than water infection," and says that "the diptera alight

upon typhoid excreta in imperfectly disinfected camp sinks and convey the bacilli upon their feet, probosces, etc., to the first dish or article of food they alight upon."[7] Celli demonstrated that typhoid bacilli, when fed to flies, were excreted by them in virulent condition.[5] What is, perhaps, one of the most interesting experiments relating to the connection between flies, water, and typhoid fever ever tried occurred at Diyatalawa camp, in the hills of Ceylon. Boer prisoners were kept there. Not a case of typhoid occurred among the soldiers until a batch of Boer prisoners arrived, one of whom was taken down with this disease. He was taken so soon after his arrival that he was supposed to have brought the infection with him. In three months there were six hundred cases in the camp. Prisoners and soldiers were separated by a barbed-wire fence. Something seemed to carry the infection through that fence. All the water came from the uninhabited mountains through an iron pipe and was passed through a Berkefeld filter before being used. Every soldier who left the camp was compelled to take this water with him. Only condensed milk was used. The senior medical officer says: "During the whole period that typhoid fever was prevailing in the prisoners' camp flies in that camp amounted almost to a plague, the military camp being also infested, but to a less extent."[8] Numerous cases can be cited of typhoid fever being carried to places where no other conceivable agent than the flies could be held responsible. In every one of these cases there is not the shadow of a doubt as to how the germs got from the flies to the patients. In every instance it was through food. The Board of Health of Glasgow, Scotland, in a review of forty years' experience, sums up the evidence for that region by saying: "If we consider the history of enteric fever in detail, we observe that everything like an epidemic prevalence has been caused by the distribution of milk."[9] Here again we observe that it is food that is held responsible. An epidemic recently occurred in Deggendorf, Germany, where both milk and water were above suspicion, and where the only ones attacked were school children who had eaten food at a certain soup house.[10]

The defenders of the theory that typhoid fever can be taken by the drinking of water are forced to ignore entirely the matter of dosage. As water is used in preparing food, in washing vessels that are to contain food, in washing places in which food is stored, and in adulterating such food as milk, it is easy to see how the exceedingly small number found in water can be multiplied sufficiently to reach a dangerous dose. Allbutt tells us that "the microorganisms responsible for a number of our commoner infective diseases belong to the group of facultative parasites, or facultative saprophytes, organisms which are capable of multiplying outside the human body."[4] They grow in various kinds of food. Fischer says: "The bacteria of typhoid, anthrax, glanders, tubercle, diphtheria, and cholera grow well, without causing any change in the appearance of milk that would suggest contamination."[11] As regards the speed of such multiplication, Professor Conn says: "Some of the species that have been carefully watched under the microscope have been found, under favorable circumstances, to grow so rapidly as to divide every half hour, or even less. The number of offspring that would result in the course of twenty-four hours at this rate is, of course, easily computed. In one day each bacterium would produce over 16,500,000 descendants, and in two days, 231,500,000,000."[12] Metchnikoff makes the rate swifter than this.[13] As there are some medical men who still seem to imagine that the entrance of one single disease-producing germ into the body presages danger it will be well to call their attention to the following statements made by our best experts. Rideal says: "They only produce dangerous results when multiplying beyond control they penetrate the blood and tissues, interfere with nutrition, set up irritation by their presence, or poison the system by their products of excretion."[14] Cabot says: "Scientific investigation demonstrated the fact that the living tissues were not passive breeding places for bacteria, but that they were able to offer a very considerable resistance to the growth of microorganisms. As Dr. Welsh has said, it took a considerable dose of the bacterial poison to produce an effect upon healthy tissues."[15] Allbutt says: "Lubarsch has shown that in order to kill a rabbit by anthrax, by injection into the circulating blood, at least 16,000 virulent bacilli of the disease must be introduced; a smaller number only produces a transient disturbance."[4] Fischer says: "Investigations have yet to be made regarding the number of germs necessary to cause infection, particularly in the case of natural infections. In our experiments on animals the smallest doses must contain thousands of bacterial cells."[11] Conn says: "Even after the bacteria get into the body it is by no means certain that they will give rise to disease, for they have now a battle to fight before they can be sure of holding their own."[12] Clemow says: "Thousands of harmful microparasites may enter the body with each breath or with each mouthful, yet, providing the protective forces are present in sufficient number and activity, the invading parasites are destroyed or rendered harmless." Fischer says "the normal gastric juice in a test tube destroys in half an hour the bacteria of cholera, typhoid and glanders, pus cocci, and the sporeless cells of anthrax."[11]

What evidence is there that ordinary hydrant, spring, well, or river water ever contains germs enough to transcend the safe amount? It is easy enough to see how food might multiply them to the danger point, but it is not evident how any person could take the disease from water that thousands are drinking without being injured in the slightest. The typhoid germs injure by their toxin. As a toxin is of the nature of a proteid it is digestible to some extent in the gastric juice. As the germs are killed in the hydrochloric acid in half an hour it would require but a short insertion to inhibit their prolific power. As the bile has likewise antiseptic powers, and as the trypsin would digest more of the toxin, they would certainly reach the intestines in a badly crippled condition unless they came as an invading host sufficiently numerous to overcome every obstacle. On reaching the intestine they would have a battle royal for their means of subsistence with the normal flora of that region. If there were still enough of them left to continue the invasion after running the gauntlet of all of these protective forces they would then have to overcome the lysins and phagocytes of the blood. In view of all these facts is it not evident that the dosage of filth germs must be quite high when they are able to run the gauntlet of so many resisting forces? When Pettenkoffer drank the cholera germs, in his celebrated defiance of the opinions of those who believed that cholera was due to the comma bacillus, he only demonstrated that the dose was too small. When typhoid, or other filth germs, get into food, in ever so small a number, there is practically no limit to the amount of poison they are able to produce, if temperature and other

conditions favor them. The mere washing of a container with polluted water can leave one or more such germs to get into milk, soup, broth, porridge, custard, etc., or to get upon meat, oysters, fish, or left-over victuals of many kinds. The swallowing of these germs at their successive stages of multiplication would do no harm until they had reached a number and virulence capable of overcoming every protective force of the body. On passing that dose they could continue their multiplication until enough were produced to create an epidemic. No other rational explanation of epidemics of cholera, diarrheal diseases, or typhoid fever has ever been advanced, and yet this one is not generally accepted, because it disagrees with the utterly unfounded theory which so many entertain, that these diseases can be given to people by the mere drinking of water. If there was the slightest evidence in the world making this popular notion probably true there might be some excuse for the stubborn way in which it is adhered to; but when the fact stands boldly forth that there is not a single peg on which to hang it, save mere blind conjecture, its tenacity stands as a marvelous proof of human conservatism.

No hypothesis is of any scientific value that fails to give a reasonable explanation of and show the relations which probably subsist between otherwise isolated, though evidently kindred facts. That hypothesis which can bring most facts into a harmonic whole is always found to be the true one. This, indeed, is, to the scientific mind, the test of its truth. In proportion to the fewness of the facts which a hypothesis is capable of causing to cohere, so is its weakness and unlikeliness to be true. A hypothesis that has existed unchallenged for years and yet has no facts of its own to harmonize, is *ipso facto*, self-condemned. The large number of facts which the food hypothesis of typhoid fever can generalize stands in remarkable contrast with the utter absence of fact as a basis of its rival. Through it, and through it alone, are we able to perceive just how the changes of the seasons, the rise and fall of temperature, the differences in the ages of the victims, the differences between country and city, the differences in the habits of people, the differences between fly season and nonfly season, the differences between people of various though related nationalities, the differences between negroes and white people, the differences between Japanese and American soldiers, the differences between cities having filtration plants and cities without such plants, the differences in different avocations, etc., produce rises and falls in our death rates. In a general way we know that cleanliness is the most important factor in sanitation, but no one has any clear conception of just how sanitation accomplishes its wonderful work, with the class of diseases we are considering, until he has perceived the exact part that food takes in their transmission. Once look at water as doing just what flies do, what dust does, what fomites do, and a flood of light is immediately thrown upon the problem. Consider these as mere seed sowers and food as the disease breeder, and for mystery we shall get a revelation, for fear we shall get confidence. It would be impossible, in this brief article, to go into all of these conditions and point out just how the food becomes responsible. Let any unbiased person assume the possibility of the food hypothesis being true, as he must do if he is at all scientific in his habits of thought, and he will be able to work out the details without difficulty. If he asks himself why warm weather increases disease of this type he will find that the water theory is dumb, while the food one gives a prompt and apparently satisfactory reply. In food warmth promotes the multiplication of pathogenic microorganisms. By increasing their numbers it increases their dosage, and thereby their danger. If he asks why negroes suffer more from such diseases than whites he will again find the water hypothesis dumb. Its supporters may contend that a difference in race immunity is the explanation. Here it will be observed that instead of bringing the facts together into a single explanation they do what the holders of false theories are always compelled to do, *i.e.* introduce a multiplicity of hypotheses. Until they can tell us what they mean by immunity they are merely trying to explain mystery with mystery. Intestinal immunity resides in conditions which evolution declares must be the most fixed, most certain, most resistant, and most uniform of our whole being. The struggle between bacteria and higher organisms must have been incessant there during all time. A variable immunity would have been wiped out millenniums ago by the utter extinction of any creature cursed with it. Not for one single instant would there be certainty of safety for them. It is perfectly safe to assume that intestinal immunity is racial immunity, or even vertebrate immunity, under all ordinary conditions of exposure, if evolution is true. A whimsical, mystical immunity may be good enough to bolster up a factless hypothesis, but it is certainly not good enough for the purposes of science. Such a fact as the following should put a quietus to so airy a speculation about immunity in the minds of all evolutionists: "The fact that several species of fossil bacteria are known from the carboniferous and other periods shows that they are among the oldest inhabitants of the earth, and were already widely distributed when the tertiary epoch and the evolution of warm-blooded creatures began." (Fischer.[11]) The poverty of the average negro, his lack of means of protecting his food with ice, his economical necessities that compel him to consume warmed-over victuals, his encouragement of flies by his careless disposal of slops and garbage, his heedless exposure of food to dust, are all factors that help to plant disease germs in his food and multiply these germs to the danger point. It has long been perceived that these habits and conditions had something to do with his susceptibility, but it was easier to refuse to think out just how they accomplished it than to try and ferret out all the connections. In the food, and in the food only, do we discover the nexus of connection. Dirty white people come in as close seconds with the negroes in their suffering from intestinal diseases, and it is easy to perceive that the food conditions that act in the one case recur in the other. Flies and dust, dirty hands and dirty vessels, by coming in immediate contact with food, sow the germs that multiply, unperceived, up to the danger dose. When we next consider the great differences that exist between cases in any epidemic, we see how the food hypothesis illuminates the situation. Mild cases mean mild doses, intensely virulent cases very large doses, and cases of every intermediate force, intermediate doses. The same dish of food partaken of by a dozen persons will produce a dozen different results. Before such a fact the water-drinking theory is again dumb. The food theory, on the contrary, gives a luminous and satisfactory explanation. In the development of germs in food they are fixed in colonies. One slice or one dish of that food may contain millions of the germs, and another taken from where the colonies were scarce or absent would contain few. The division would give all degrees. In the development of germs in milk, certain cans could become infected in a carload, while other cans of the same supply might

escape. Customers receiving their supply from the infected cans might have the disease, while others getting the same dealer's milk would escape. The cans could be infected from the water used in washing them and the dairymen be innocent of any intent to palm off bad milk. Milk users who happened to be served with the infected milk would fare differently from it, according as they used small amounts of that milk in hot tea, or large amounts of it as a beverage. The dose would give results. Various kinds of food vary in their ability to develop typhoid. A milk-using people would in their ice-cream, puddings, custards, charlotte russes, merangue pie, and other delicacies into which uncooked milk enters, be in vastly greater danger from typhoid fever than would a people who use no milk because of their religious prejudices or national habits. In the war in Manchuria the Japanese lost only one-sixth as many cases from typhoid fever and dysentery as did the Russians. The differences in the character and the method of care of the food of the two nations amply accounts for this result without our going into ecstasies regarding the wonderful care taken by the little brown men to prevent disease. The Russian soldiers had boiled and filtered water as well as the Japanese. What the former did not have was food that resisted the development of germ colonies as did that of the latter. When a Russian soldier had rice, pudding, porridge, pies, recooked potatoes, etc., they were often mixed with milk. By exposure to dust or flies they became excellent culture media for the germs these bore to them. When the Japanese soldier had his rice or barley, it was not administered as a slop, but in a condition of relative solidity, which gave it some degree of resisting power to the development of germs. They ate little meat and had no soups or broths. They drank no milk. The United States surgeon assigned to study the hygienic conditions of the Japanese army while in the field, reported, on his return home, that "there was a constant use of creosote pills, the boxes of which were marked: 'To defeat the Russians, take one pill three times a day.'"[18] In the care and character of food the two armies were quite unlike. In the care and character of the water there was little or no difference between them. All food eaten by the Japanese soldiers who used the creosote pills was treated to preservatives so that to the disinfecting action of the gastric juice was added the disinfecting action of the creosote. Did this continuous and universal use of a preservative injure or benefit them in their struggle on the battlefield. Three times a day all that they ate was embalmed. Kitasato, the great Japanese bacteriologist, was doubtlessly the originator of this strange idea, as he was the army's inspiration in matters of this kind. As he was educated in Germany along with Behring we can see in this a unity of thought between them when the latter gentleman, in defiance of popular opinion, published his book on "The Suppression of Tuberculosis," which teaches that this disease may be subdued by the use of a potent preservative in milk. When Koch advocated the use of quinine for the suppression of tropical malaria he was inspired by practically the same idea. Is it not strange that three of the best qualified bacteriologists in the world should entertain such heretical ideas concerning the use of antiseptic substances? Is it not still more strange that vital statistics always seem to confirm their contentions?

THE PROPER LIMITATIONS OF THE MEDICAL AND SURGICAL TREATMENT OF GASTRIC ULCER.*

By G. W. McCASKEY, A.M., M.D.,

Fort Wayne, Indiana.

Professor of Medicine, Indiana Medical College, Department of Purdue University; Physician in Chief to Hope Hospital.

Gastric ulcer is one of those diseases in the treatment of which internal medicine and surgery meet. Their precise indications are in the formative stage and are, naturally, to some extent a matter of individual judgment, and it is not at all strange, therefore, that striking differences of opinion should exist. Dogmatism should find no place in the discussion, and any claim on the part of internists that surgery has not an important rôle to play in the treatment of gastric ulcer is clearly wrong, while, on the other hand, the contention that gastric ulcer, like appendicitis, is essentially a surgical disease is, in my opinion, equally wrong. The truth lies between these two extreme propositions. The moment seems opportune briefly to review the results of these diverse modes of procedure, with the hope that each interchange of views will help to delimit their scope and indications. That the so-called medical treatment of gastric ulcer has been in some respects an unsatisfactory chapter, must be freely admitted. Brinton held that only about one-half of all cases were curable, while Lebert only found a mortality of 8 per cent., and Rosenheim of 10 per cent. It has been clearly shown by Fenwick that the high mortality of gastric ulcer maintained by Brinton and Debove and Remond was due to faulty methods of analysis, as in not less than 40 per cent. of the fatal cases of the latter writers tuberculosis was the real cause of death. The striking influence of proper methods and favorable conditions upon the outcome of gastric ulcer is well illustrated by the statement of Fenwick, that 17 per cent. of the cases of gastric ulcer occurring in his hospital clinic died from the immediate results of gastric ulcer, while in private practice, where cases could be better controlled and environment was more favorable, the mortality did not exceed 4 per cent. Out of 556 cases treated by Leube, the cures were 74 per cent. and the mortality only 2.4 per cent., and it may be safely stated that when the diagnosis is made early and cases properly treated, that the mortality need not

*Read before the Indiana State Medical Society, May 23, 1906.

exceed 5 per cent. Between the 74 per cent. that make a complete recovery and the 4 or 5 per cent. that die, there is a considerable group of cases in which the result is unsatisfactory and the cure incomplete, and it is with reference to this group of cases as well as the fatal ones that the question of surgery applies.

As a matter of fact, in spite of the enormous amount of work that has been done and the records of which have been published, we are without adequate and satisfactory data by which to judge the efficacy and the dangers of both the medical and surgical treatment of gastric ulcer. With reference to the surgical treatment, its advent is too recent to permit of final judgment, while the same difficulties must be encountered in following up and analyzing cases as have beset the experience from a medical point of view. What is needed is a large series of cases of all sorts, carefully treated on a uniform plan. This really has been done, but beyond this it is necessary to follow both the cases which are apparently cured and those which are simply improved for a long period of time, which in the nature of things is possible only with a certain proportion of cases. There is no doubt whatever that many cases which are apparently cured by medical treatment will subsequently have a relapse, while presumably a much larger proportion of those cases which are only improved will suffer subsequent exacerbations more or less serious in character. While this is admittedly true, it remains to be shown that it will not be in a large measure true with reference to the cases treated surgically. It remains to be shown that a case cured surgically is any more completely or permanently cured than one which is cured without surgical treatment. The principal object of surgical treatment, and the trend of recent surgical experience, is to make physiological rest of the organ more nearly the exclusive object. That such rest can be secured over a long period of time more absolutely by means of a gastroenterostomy than by any other means there is not the shadow of a doubt. The opening of the abdomen, however, and the gastrointestinal anastomosis, cannot be viewed as a trivial affair, and can be justified only on the ground of either protracted disability and suffering or danger to the life of the patient, and the real question is whether such a degree of physiological rest as is requisite, for the healing of the ulcer cannot be secured and maintained without the hazards and nervous shock of the operating table. The mortality of the Mayos in 89 uncomplicated gastroenterostomies, reported in 1902, was 7.8 per cent. Munroe in 1904 reported 23 cases of gastroenterostomy for nonmalignant stenosis, with a mortality of over 20 per cent. These cases were unusually unfavorable ones. On the other hand, Moynihan reported 37 cases with no deaths. It is obvious from these and similar records that gastroenterostomy is not without hazard and is not to be lightly advised.

Since the days of Cruveilhier up to the advent of gastric surgery, the principal object of the clinician, attained in various ways, has been to give the organ the greatest degree of rest consistent with the integrity of general nutrition. For a few days or a week this can be accomplished for all practical purposes quite as well by medical as by surgical means, with the possible exception of a few cases in which there is a continuous hypersecretion in the intervals of digestion. The experience of clinicians has shown, and especially the very large experience of Leube, that in about three-fourths of all cases the healing process will have begun and will have received such an impetus during this period of rest, supported, of course, by rectal alimentation, that suitable liquid nourishment may then be taken into the stomach without interfering with the healing process. For this 75 per cent., then, if they could be discriminated from the remaining 25 per cent., surgical treatment would be an absolutely unwarranted procedure. What is needed more than anything else in order more clearly to define the scope and efficacy of medical treatment, is a fuller and more complete control of the something like 20 per cent. of patients who are discharged improved but not symptomatically cured. This is vitally important for two reasons, first, to determine the final issues in such cases, and second, to secure such control of diet and environment as will give those patients the best possible chance for recovery. There can be no reasonable doubt that a considerable proportion of this 20 per cent. do badly because of dietetic indiscretions, practised either openly or surreptitiously. One of my patients, for instance, who was apparently following a strict diet and not doing very well, was detected by another patient boarding at the same place eating the indiscriminate and not very well prepared food of an ordinary boarding house, in which arrangements had been made for a suitable diet. These are factors which influence the final results of medical treatment no more than they would of surgical.

There are other factors which tend to throw uncertainty upon the statistics, one of which is the possible fallacy of symptomatic cure. Robson and Moynihan put it as follows: "It is useful to hold in view the course of an ulcer of the leg, which, directly the healing stage has arrived, becomes free from pain. But this neither indicates that healing is completed, nor that care may cease." It is only fair to say, however, that the parallelism between an ulcer of the leg and ulcer of the stomach is certainly not any greater than that which could exist between a straight and curved line. The ulcer of the leg can be cleansed, treated with a dry dressing, and remain subsequently free from irritation, and might easily, therefore, be free from symptoms, while an ulcer of the stomach, the functions of which cannot be suspended with impunity, as are those of the leg, is subjected to varying grades of irritation, and the absence of symptoms has therefore much greater significance than it would have in the case of a leg ulcer. Nevertheless, abundant clinical observation proves beyond doubt that owing to the personal equation of the patient or other causes, gastric ulcer may exist absolutely latent, and we must therefore admit the possibility that some of the cases which are symptomatically cured are not really so. Here again, however, this supposition will apply, so far as I can see, with absolutely the same force to a case treated surgically as to a case treated medically.

The experience of J. W. Russel is valuable in this connection, in that it traces the after-history of 47 cases for periods of two to thirteen years, with an immediate mortality of 2.1 per cent. and recovery in 42.6 per cent. Of the 42.6 per cent. that recovered, 27.7 per cent. had but a single attack, while 14.9 per cent. recovered after one or more relapses. Of the remainder, 15 per cent. had repeated attacks, but were free from symptoms in the intervals, while 30 per cent. had more or less continuous pain. It appears from his experience

that something more than one-fourth of the cases have more than one attack, while Sears has found recurrence in 60 per cent., which is certainly exceptional. These facts certainly have an important bearing on the question of the permanence of the cure produced by any means whatever, but probably will be found to apply equally to medical and surgical methods. Sears, in fact, admits that surgery does not always cure, and that recurrence has followed surgical treatment.

It is not my intention to enter into a full discussion of the various means of treatment from a medical point of view, although I will incidentally state the method which has given the best results in my own personal experience. One question cannot well be passed without a brief discussion, and that is, Shall food be given from the beginning of the treatment or not? The method of Leube, beginning with a period of starvation and rectal feeding, is too well known to require discussion. Others in recent years have advocated giving the patient at once properly selected food for the stomach. Among the most interesting contributions along this line is the well-known comparative series of cases reported by Greenough and Joslin. These two series of cases occurred in two different services of the Massachusetts General Hospital. In one series of cases rectal feeding was uniformly followed for the first few days, while in the other it was limited to the severer cases, lime water and milk being given from the start to all others. Of the cases who received rectal feeding from the first the recovery was 32 per cent., while of those who received food by the mouth from the beginning of treatment 44 per cent. were cured. The adoption of rectal feeding in the severer cases of the second group, however, vitiates the statistics as a whole, but probably tends to show that no iron-clad rule is applicable to all cases, and that the treatment should be individualized.

It seems to me that chemical pathology has pointed the way, or, rather, has furnished some of the indications for the treatment of gastric ulcer, as it has of so many other morbid conditions. The formation of gastric ulcer, whatever may be the etiological factors, is a process of cytolysis. Excepting that it occurs in the fixed tissue of the stomach wall rather than in the floating cells of the blood, it is for the most part entirely analogous to the phenomena of hemolysis which have been so extensively studied within the last few years. The occurrence of cytolysis under the influence of a lysin is prevented by certain chemical products known as antibodies, the formation of which is stimulated by the presence of a lysin, but which presupposes as a *sine qua non* the integrity of the nutritional processes of the body. Perhaps the cytolysin which destroys the tissue in the circumscribed area of the gastric wall which is to become the seat of an ulcer may be the gastric juice, or it may be the gastric juice plus something else. There are two conditions which may make this cytolysis possible, first, a lowered resistance of the circumscribed area of tissue from an unknown cause, whether thrombus or something else; and second, and perhaps coupled with the first, a failure on the part of the antibodies of the circulating fluid which bathes the cells to do their work. With the first of these conditions it is not my intention to deal. The second is fundamental in a therapeutic program, and is vital to the limitations of the ulcerative process. That it is dependent upon proper nutrition with all that this implies, is perfectly obvious, and its bearing upon the question of properly feeding patients suffering from gastric ulcer need scarcely be pointed out. It seems to me perfectly clear, when we take into account the widely different states of nutrition met with in the various cases of gastric ulcer, that a plan of treatment suitable to one case might easily be entirely improper for the next. Patients that are fairly well nourished have, as we know, a certain amount of reserve nutrient material stored up within the organism, upon which they can draw for a limited time, and if this is supplemented by properly directed rectal feeding, there seems to be no reason why in such patients the ulcer should not be given the benefit of complete physiological rest, as it can be done without substantially interfering with the chemical processes of nutrition which produce those protecting chemical bodies above referred to. On the other hand, patients who have become greatly emaciated and in whom the chemical processes of nutrition are necessarily greatly impaired, the reserve supply of nutritive material has been more or less completely used up, and the chemical processes of the body, both constructive and protective, correspondingly weakened, and anything approaching starvation treatment in such a case is to be viewed with great apprehension, and is liable to do more harm than good. What I would plead for, then, would be a differentiation of the cases, starvation with rectal feeding for various lengths of time in those cases to which it seems adapted, and earlier and perhaps instant feeding in those in which it is apparently demanded.

In the average case, my method has been to put the patient to bed from three to six days, with absolute starvation so far as stomach feeding is concerned, and give at the same time systematic rectal alimentation. If necessary, at the outset the stomach is cleansed with a 1 per cent. solution of sodium bicarbonate, but this is only indicated when there is an excess of mucus or other secretion. Immediately following this lavage or without it, a single large dose of bismuth subnitrate, say about 90 grains, is given. This is repeated each morning if the conditions require lavage. At the expiration of the starvation period, which is continued for whatever length of time may seem proper in the individual case, feeding is resumed in general accordance with the Leube plan. In cases, however, with greatly impaired nutrition, milk and lime water, or better egg albumin, should, I believe, be given from the onset, supplemented, of course, by rectal alimentation.

I wish in conclusion to call attention to a few of the unfavorable aspects of the surgical treatment of gastric ulcer. One of these is the occurrence of acute perforating jejunal ulcer, which occasionally follows gastroenterostomy. Another feature which cannot be entirely free from objection is the permanent fixation which gastroenterostomy entails between the stomach and intestine. It cannot be otherwise than that such immobilization interferes with the motility of both organs, and if closure of the anastomotic opening occurs, as has been found by both Moynihan and Czerny, the motility of the stomach is permanently crippled. On the other hand, as long as the anastomotic opening remains patent, the observations of Hartman and Soupalt have shown that in all cases of gastroenterostomy, either anterior or posterior, both bile and pancreatic juice are regurgitated into the stomach, a phenomenon which may not be serious, but which cannot be viewed with entire satisfaction.

Now, it appears to me that the logical conclusion from all these facts is that every case of gastric ulcer ought, if possible, to have the benefit of a carefully conducted medical treatment at the hands of an intelligent practitioner before the question of surgery has been raised at all. In other words, the case is a medical one and not a surgical one, at the outset. When it comes to a recurrence, which the statistics go to show occurs in a large number of cases, the question is not quite so clear, but I am inclined to think that, barring severe symptoms which do not yield to the rest treatment, the patient should have at least a second chance at medical treatment. This conclusion ought to stand until it has been shown that recurrence does not follow surgical treatment, as precisely the contrary now appears to be the fact. Nevertheless there is a group of cases which may either grow larger or smaller with increasing experience, in which a gastroenterostomy is clearly the proper line of treatment. It is, perhaps, impossible at the present time to formulate accurately the conditions which would justify the procedure. Perhaps repeated severe hemorrhages may be placed among the list, but not as a curative measure for the hemorrhage, as experienced so far in emergency operations for hemorrhage scarcely justifies its repetition. Mumford and Stone (p. 156), who cannot be suspected of a medical bias, say: "Scattered reports from numerous surgeons teach conclusively the lesson that emergency operations to check violent gastric hemorrhage almost always end disastrously." This is very discouraging, but it would seem that for the present we must accept the logic of facts and consider a patient suffering from severe gastric hemorrhage safer with medical than with operative treatment. Severe and intractable symptoms, aside from hemorrhage, especially pain and vomiting, are certainly among the factors to be considered. A large proportion of cases, however, in which these symptoms are very severe, make good recoveries under medical treatment. The precise length of time during which medical treatment should be followed in intractable cases before surgical intervention is invoked cannot be decided by any hard-and-fast rule. The entire aspect of the case is quite as much a factor as time, and the two things must be taken together in the final analysis, and the resulting conclusion must be simply the judgment of the clinician, based upon all available facts. We must bear in mind the influences which the state of general nutrition has upon the healing processes everywhere through the chemical composition of the blood, and a case may not be symptomatically cured because the general nutrition is not up to the proper standard. Where it is possible in the face of the digestive disorders to put the patient on a proper nutritional plane, this ought certainly to be done, and then sufficient time given before labeling the case not amenable to medical treatment.

There is one other thing that I would especially plead for in these cases, both in the preliminary diagnosis, during the progress of the treatment, and as a criterion of end results, and that is repeated systematic scientific study of stomach secretion and motility, and the material obtained from the fasting stomach. I doubt very much if a latent ulcer can exist unrecognized in the face of such a study. The character of the cellular débris, the bacteriological content, as shown both by stained specimens and fermentative tests, are all points of the most vital importance in reaching a conclusion, although they can only be rationally considered in conjunction with the anamnesis and complete clinical picture.

There is much in the current literature of surgery of the stomach that shows an apparent lack of appreciation of the gravity of an abdominal section which is not altogether represented by the mortality, although this is not entirely nil.

As bearing on the question of time during which a case should have treatment before the intervention of surgery, Mumford and Stone quote with disapproval, as being too broad a generalization, the statement of a "Clear-headed surgeon" that: "If you have a patient who has suffered for two years from a chronic dyspepsia, unrelieved by internal treatment, you may fairly say that his case is probably a surgical one"; which emphasizes the remark that I have already made that no hard-and-fast rule, so far as time is concerned, can be made, but that a critical study of the case by a competent internist, in conjunction, perhaps, with a consulting surgeon, is the only safe ground upon which to rest a decision, as the time may be two weeks or two years. I will conclude with their further opinion, which has my entire approval, that we cannot say of gastric ulcer what has come to be said of appendicitis, that it is purely a surgical disease, but that in many instances it is so, and that the judgment and possibly the services of a surgeon are desirable in a certain proportion of cases.

407 West Main Street.

THE HEALTH AND MORTALITY OF THE COTTON-MILL OPERATIVES OF BLACKBURN, ENG.

By FREDERICK S. CRUM.

East Orange, N. J.

One of the most instructive examples of the good use that may be made of local mortality returns is furnished by the Annual Reports of the Medical Officer of Health of Blackburn, England. Blackburn borough is in the very heart of the cotton mill district of England, and embraced in 1901 a larger number of cotton-mill operatives than any other single borough in the United Kingdom. In 1901 there were 38,551 cotton-mill operatives in Blackburn borough, representing about 38 per cent. of the total population of ages ten and upwards. In 1891 the proportion was still greater, or about 42 per cent. In fact, for at least a hundred years the cotton industry has been the all-important manufacture in Blackburn. In 1851, "46.5 per cent. of all the males, and 35 per cent. of the females above the age of twenty years were employed in the cotton mills," and in addition, "a considerable number of young persons of both sexes under twenty years."

Although cotton-mill operatives have thus constituted the most important element of Blackburn's population for a long period of years, the careful compilation of their mortality statistics, as distinct from those of the borough population as a whole, was not begun until 1890. The health of the employees, however, had long before attracted considerable attention, and among other references we find the following in the Medical Reports of the Privy Council for 1861, in a discussion of the health conditions of the cotton operatives of Blackburn. "The great prevalence of pulmonary diseases among the inhabitants of Blackburn had not escaped the notice of the resi-

dent practitioners. Mr. Wraith, of Over Darwen, certifying surgeon of factories, and also parochial medical officer for that district of the Blackburn Union, had observed for maore than twenty years the great prevalence of bronchitis and phthisis. He had specially noticed that operatives employed in the carding-rooms suffer from these diseases, and he attributed the circumstance to their inhaling dust and flue. . . . In Dr. Grime's opinion, inhaling dust and flue diffused through the atmosphere of the card rooms, is the primary cause of the prevalence of pulmonary diseases among this class of operatives, being out of all proportion more frequent among those who work in card rooms than among other occupied persons."

As a result of these discussions and with a view to determine the relative mortality of cotton operatives in the principal branches of the manufacture in a more definite manner than had previously been possible, Dr. Barwise, the local Medical Officer of Health of Blackburn, began, in 1890, the careful compilation of the mortality statistics of the cotton operatives making distinction of age and separating the more sharply defined groups of occupations. From 1891 to 1901, both years inclusive, the work initiated by Dr. Barwise was continued by Dr. James Wheatley his successor. In 1902 Dr. Alfred Greenwood was appointed Medical Officer of Health of Blackburn, and the work has since been carried on under his direction.

In the annual report of the Medical Officer of Health for 1892 use was made of the population returns by occupation, compiled from the Census books of 1891, and comparative death rates of the different classes of operatives were, for the first time, available. The mortality figures were given for all causes, consumption, and respiratory diseases, with distinction of card room hands, spinners, winders and warpers, and weavers. These primary distinctions have been continued since 1890, and in 1893 the returns were carried back a year to include 1889, so that now there are available in the Annual Reports of the Medical Officer of Health of Blackburn the mortality statistics of a large number of cotton-mill operatives for a seventeen-year period, 1889-1905, representing a total mortality among the four well-defined groups of operatives, aged fifteen and over, of 4,616.

Unfortunately, distinction is not made of sex, except in the mortality of weavers from all causes. This separation was first made in the Annual Report for 1895, and has since been continued. Appendices to the reports give the mortality of the operatives from various causes, but without distinction of sex. Thus far the rates have not been worked out for other causes than consumption and respiratory diseases, as the numbers are not yet sufficiently large to make such rates of determining value. In time, however, these detail figures will be of the greatest possible value in helping to determine the improvements in health, if any, of the operatives, and the causes of death other than consumption and respiratory diseases to which cotton-mill operatives are specially liable. It is to be hoped also that the occupations will be given in more detail in some of the future reports.

A brief description of the main processes of cotton cloth manufacture is necessary to a full understanding of the variations in the number of persons employed and in the comparative mortality rates. In Blackburn the cotton is worked up from the raw bales into the finished products. Not all of the cotton for weaving is spun in Blackburn, however, and the town is specially devoted to the weaving branch of the industry. There are very few shoddy mills in Blackburn, and the persons thus employed are so few as not to affect the whole. This statement is made because the employees of shoddy mills are generally considered to be among the most unhealthy of all cotton-mill operatives.

Preliminary to weaving, the raw cotton is cleansed in the picking and blowing rooms; it is then carded and combed in the card room; it is next spun, and then come the processes of winding and warping, followed by the weaving of the yarn into cloth. In the picking and blowing rooms much dust is created, and this is generally considered to be the principal ill-health producing factor in those processes. Relatively few hands are engaged in this work. In the card room the cotton is carded and combed, and these processes also create considerable dust. The cards and combs require to be cleaned frequently to prevent clogging, and the teeth also require to be ground occasionally. If this latter work is not done automatically the work is considered to be very hazardous because of the metallic dust engendered by the operation. Despite all precautions to enclose the carding machines, or engines, as tightly as possible, much dust escapes into the atmosphere of the card rooms, to the detriment of the employees' health.

From the carding machines the cotton is delivered to slubbing and roving frames where it is given a preliminary twist. It is then ready for the spinning frames. These are of three principal kinds—mule, throstle, and ring. The spinning done on mule frames requires male attendants as the work is heavy and demands more than a woman's strength. The dust factor is of importance in the spinning-room, but the high temperature, lack of proper ventilation, and liability to accident are also features of importance from the viewpoint of the health and mortality of the employees.

The spun yarn is next wound upon bobbins by "winders" and from the bobbins it is placed upon beams by "warpers." The warp is then "sized" and prepared for the looms by "reachers" and "drawers." There is some dust present in the atmosphere of the winding and warping rooms, and the ventilation, generally speaking, is unsatisfactory.

These preliminary processes are usually carried on in roomy shops, but notwithstanding the considerable air-space per head, the atmosphere is frequently by no means pure. In the spinning rooms the temperature is often very high and the air heavily charged with carbonic acid (carbon dioxide). Spinning is carried on in many-storied buildings in which light and fresh air have to be secured almost entirely from the sides. For several reasons very little fresh air has been provided in the spinning rooms in the past. "By excluding the outside air, the rooms can generally be kept at a good spinning temperature simply by the friction of the machinery, and at the same time particles of soot are prevented from entering and damaging the yarn."

The weaving of cotton cloth in England is principally carried on in one-story buildings, called sheds, and, as dampness conduces to good weaving, the sheds are usually located in damp places, and the floors are frequently flagstone laid directly on the earth. "The walls are without windows, and where openings are provided for ventilation, they are usually closed. All the light and most of the fresh air have to gain admittance through the roof, and little direct sunlight is admitted to the weaving shed." A large proportion of the weaving sheds of England are artificially moistened by the injection of steam into the atmosphere. Previous to 1889 there was no

legal limit to the artificial moisture infused in these sheds, and as a result very bitter complaints were made that excessive quantities of steam were injected into the atmosphere of the sheds, to the very serious detriment of the health of the weavers. As a direct consequence of the agitation over this feature of the industry, Parliament passed the Cotton Cloth Factories Act of 1889. This Act required among other things that 600 cubic feet of fresh air per head per hour be admitted into artificially moistened cotton cloth weaving sheds. This standard, a vast improvement over previous conditions, was condemned as insufficient by a Departmental Committee appointed a few years later to investigate the subject. This Committee, after making an exhaustive inquiry, recommended in 1897 that in no part of cotton cloth factories (artificially moistened) should the proportion of carbonic acid (carbon dioxide) in the air be greater than nine volumes of carbonic acid to every 10,000 volumes of air. This recommendation was embodied in the Cotton Cloth Factories Act of 1897, and became effective through an Order of the Secretary of State issued in February, 1898. This standard of ventilation is of the greatest importance as it represents the first attempt in the history of factory legislation to secure a standard of ventilation based upon the actual purity of the atmosphere breathed by the workers. This feature of the Act of 1897 has caused much discussion. It is claimed by many that the standard is too high to be maintained, especially on foggy days, or when the rooms are lighted by gas. On the other hand, there is evidence to show that many of the sheds are kept well within the standard, and that the Act as thus far enforced has resulted beneficially to the employees. In this connection, however, it may be stated that another Departmental Committee appointed to inquire into the ventilation of factories and workshops, recommended in 1902 " that the proportion of carbonic acid (in factories and workshops not otherwise dealt with) at the breathing level, except on foggy days, or when gas or oil is used for lighting, shall not rise, during daylight, or after dark when only electric light is used, beyond twelve volumes per 10,000 of air, and when gas or oil is used the proportion shall not exceed twenty volumes unless carbonic acid is produced in other ways than by respiration or combustion, as in breweries, etc."

TABLE I.

COTTON-MILL OPERATIVES.*

Blackburn, Eng., 1901.

NUMBER AND PERCENTAGE OF THE TOTAL POPULATION.

AGES	NO. OF OPERATIVES			PER CENT. OF TOTAL POPULATION IN COTTON MILLS

15 and over..	12,802	21,422	34,224	32.1	43.9	38.6

*Including unemployed retired operatives.

With these preliminary observations we pass to a consideration of the mortality of cotton operatives, based upon the number employed in the Blackburn mills in 1891 and 1901, and the deaths as recorded in the Annual Reports of the Medical Officer of Health during the period 1889-1905.

Table I presents the salient facts of the population of Blackburn from the point of view of the total number of cotton-mill operatives, who were either actually employed in the cotton mills in 1901, or who were retired operatives without other employment.

The above table brings out some very significant facts. It is shown that of the total male population of ages ten and over, 31.2 per cent. were either in the cotton mills or had retired without other employment. The retired male operatives numbered 375, and we therefore have it that about 30 per cent. of the male population of working ages were actively employed in the cotton mills of Blackburn in 1901. Of the total female population of ages ten and over, 42.9 were cotton operatives, active or retired. The number returned as retired operatives was 284, and the number actually in the mills embraced about 41 per cent. of the total female population of ages ten and over. Of the female employees in 1901 3,148, or over 13 per cent. of the total, were either married or widowed. Reference to the table shows that the largest proportion of the population is in the mills at ages 15 to 24. At this period of life 36.4 per cent. of the males, and 68.9 per cent. of the females of Blackburn were in the cotton mills. This fact is significant because this age period and the one following (25 to 34) represent the time of life when consumption is most prevalent, and, generally speaking, the mortality from that disease highest.

Another fact to be noted is the considerable actual number and the relatively large proportion of the total population of ages 10 to 14 who are in the cotton mills. Not only are comparatively large numbers of children of ages 10 to 14 employed in textile factories, but the hours of labor for adults and for many children of ages 13 to 16 are from 6 A.M to 6 P.M., with a Saturday half-day from 6 A.M to 1 P.M. It is only fair to add, however, that applicants for positions in the textile and other mills, of ages 10 to 16 are required to have "certificates of fitness" from certifying surgeons, and practically all of the children of ages 10 to 13 work only half-time.

Table II gives a further analysis of the cotton-mill operatives of Blackburn. The facts brought out are important to keep in mind in any study of the mortality statistics of the operatives as the age, sex, and occupational groupings are of the utmost importance in any comparison of the death rates.

TABLE II.

COTTON-MILL OPERATIVES.

Blackburn, Eng., 1901.

BY AGE, SEX, AND FOUR PRINCIPAL GROUPS OF OCCUPATIONS.

CARD ROOM HANDS.

65 and over..	82	2	84	4.4	0.4	3.6
10 and over..	1,882	446	2,328	100.0	100.0	100.0

WINDERS AND WARPERS

10–14.....	279	342	621	17.3	6.7	9.2
15–24.....	400	2,042	2,442	24.8	39.9	36.3
25–34.....	349	1,343	1,692	21.7	26.2	25.1
35–44.....	314	761	1,075	19.5	14.9	16.0
45–54.....	185	411	596	11.5	8.0	8.9
55–64.....	57	154	211	3.6	3.0	3.1
65 and over..	26	67	93	1.6	1.3	1.4
10 and over..	1,610	5,120	6,730	100.0	100.0	100.0

WEAVERS

10–14.....	969	2,138	3,107	11.7	12.6	12.3
15–24.....	2,900	7,313	10,213	35.0	43.1	40.4
25–34.....	1,832	4,370	6,202	22.1	25.7	24.5
35–44.....	1,266	2,128	3,394	15.3	12.5	13.4
45–54.....	708	710	1,418	8.5	4.2	5.6
55–64.....	434	219	653	5.2	1.3	2.6
65 and over..	184	100	284	2.2	0.6	1.2
10 and over..	8,293	16,978	25,271	100.0	100.0	100.0

Extended comment upon the foregoing table is not necessary at this point. In the four specified departments, in which the great majority of the operatives are employed, the total number of employees was 36,285, of which 5.4 per cent. were in the card rooms, 6.4 per cent. in the spinning rooms, 18.6 per cent. in the winding and warping rooms, and 69.6 or more than two-thirds of the total in the weaving sheds. The female operatives outnumbered the males in all departments except spinning, where the males were in excess in about the proportion of 4 to 1. This is due to the strength necessary in mule spinning. In the other departments quickness and deftness are the prime requisites, and female labor is therefore in great demand.

TABLE III.—*Continued.*

Table III shows the actual number of deaths from all causes, consumption and respiratory diseases, among the four principal groups of cotton-mill operatives during the seventeen-year period for which the facts are now available. It will be noted that the deaths when considered by age periods are still comparatively few in number, and this is particularly true as regards card room hands, spinners, and winders, and warpers, when the mortality from consumption and respiratory diseases is considered. The mortality is large enough, however, to be of some value for these groups of employees. The paucity of these data for card room hands and spinners emphasizes the need of similar statistics for such towns as Bolton and Oldham, where cotton spinning and the preliminary processes are the all-important branches of the cotton industry, just as weaving is the specialty in Blackburn.

Table IV shows the comparative mortality rates of carders, spinners, winders and warpers, and weavers, from all causes, from consumption, and from respiratory diseases, with distinction of age. The mortality returns are limited to ages 15 and over and it is therefore impossible to calculate the rates for ages 10-14 in the tables which follow. The census returns of 1891 were applied to the deaths from 1889 to 1897, and the census returns of 1901 were applied to the deaths from 1898 to 1905.

TABLE IV.

COMPARATIVE MORTALITY RATES OF COTTON-MILL OPERATIVES.

Blackburn, Eng., 1889-1905.

(RATES PER 1,000 EMPLOYEES OF SPECIFIED AGES.)

AGES	Card Room Hands	Spinners	Winders and Warpers	Weavers	All Occupied Males, Eng. & Wales, 1890–92

25–34.....	5.1	7.7	6.4	4.8	7.3
35–44.....	9.2	10.3	9.4	9.1	12.4
45–54.....	19.2	25.7	17.8	14.9	20.7
55–64.....	29.2	43.7	33.5	44.7	36.7
65 and over....	66.2	177.7	124.4	139.5	102.3
CONSUMPTION					
15–24.....	1.0	1.3	1.2	1.1	1.3
25–34.....	2.0	2.5	2.4	2.4	2.6
35–44.....	2.3	2.8	1.7	1.9	3.4
45–54.....	3.0	2.4	1.3	1.8	3.4
55–64.....	8.0	0.8	1.0	2.8	2.7
65 and over.....		1.8	2.6	0.9	1.5
RESPIRATORY DISEASES					
15–24.....	0.4	0.8	0.7	0.4	0.4
25–34.....	0.6	1.0	0.5	0.7	1.1
35–44.....	1.6	2.2	2.3	1.8	2.5
45–54.....	7.8	7.0	4.7	4.8	5.2
55–64.....	7.1	17.8	0.8	15.1	10.3
65 and over....	24.3	48.8	32.8	35.6	25.0

The final column in the above table is inserted for comparison, principally with spinners, the larger proportion of whom are males. The rates taken together are in many respects suggestive of the very different conditions which exist in the various departments of the cotton cloth manufacture. Contrary to what might have been expected, the death rates from all causes and also from consumption and respiratory diseases, except at the higher ages, are comparatively low among the card room hands. The rates do not appear to be in excess of those for spinners, winders and warpers, and weavers at ages under thirty-five, but the mortality from consumption among card hands is excessive at ages thirty-five and over as compared with the rates for winders and warpers, and weavers.

Spinners are subject to a high mortality from consumption and respiratory diseases at ages over thirty-five as compared with winders and warper and weavers, and their mortality is also excessive as compared with all occupied males in England and Wales.

Weavers have a comparatively favorable mortality, and winders and warpers share this favorable showing. This comparatively good showing, particularly at the higher ages, is probably in part to be explained by the fact that some of the married female operatives who retire because of illness are reported as housewives when they finally die. This reason has been suggested in the reports of the Medical Officer of Health, and it seems to be supported by the fact that the female weavers have a much lower mortality at certain ages than male weavers. This point, however, will be considered at length in the proper place.

Table V presents a comparison of the mortality of the four principal groups of cotton-mill operatives, from consumption and respiratory diseases. The last column gives the similar percentages for the white population of the Registration Area of the United States as reported in the Census of 1900.

15–24	11.1	15.6	15.3	10.8	9.5
25–34	11.4	24.4	8.5	14.0	10.4
35–44	17.5	21.3	24.0	19.3	12.2
45–54	40.6	38.8	26.5	32.0	13.4
55–64	24.2	19.7	29.3	33.7	14.6
65 and over	30.7	27.5	26.4	25.5	14.7

The foregoing table shows that consumption is by far the most important cause of death among weavers and particularly of ages 15 to 44, when the largest numbers are engaged at this occupation (See Table II). It is a more important factor in the mortality of card room hands than in the mortality of spinners. This fact may be due to the very different sex distribution, for the mortality from consumption among the females may be relatively higher than among the males, and the great majority of the card room hands are females, while the males predominate among the spinners (See Table II). This point cannot be definitely settled until distinction is made of sex in the mortality returns.

Table VI presents the comparative mortality rates of the cotton operatives of Blackburn, with a view to determine if there has been any noticeable improvement in 1898-1905 as compared with 1889-1897. The period 1889-1897 represents the time that the Cotton Cloth Factories Act of 1889 was in force, and 1898-1905 represents the time that the Act of 1897 has been in effect.

TABLE VI

COMPARATIVE MORTALITY RATES, COTTON-MILL OPERATIVES.

Blackburn, Eng., 1889-97 and 1898-1905.

(RATES PER 1,000 EMPLOYEES OF SPECIFIED AGES.)

CARD ROOM HANDS

Ages	All Causes		Consumption		Respiratory Diseases

65 and over..	189.3	114.9		1.3	60.4	22.8

A careful study of the preceding table will show that the mortality rates indicate a decided improvement in the health and longevity of the cotton operatives of Blackburn, in recent years. This

improvement is noticeable in all four of the principal departments of the cotton cloth manufacture. Curiously enough one of the most important exceptions to the general rule is found in the mortality from consumption among weavers of ages 25 to 34. At this age period there seems to have been an increase in the mortality from consumption, although there was a marked decline in the mortality from respiratory diseases and also from all causes. Some of the apparent discrepancies may be due to the possibly defective census returns and to the fact, previously noted, that the mortality returns of female operatives are more likely to be deficient than are those of males. At ages 55-64 and 65 and over the comparison is of least value because of the disturbing element of the retired operatives. These are included in the deaths, but in 1891 the trade census of Blackburn apparently did not include the retired operatives. As few operatives retire below the age of 55 the rates are fairly comparable at the earlier ages, but at ages over 55 the rates for the period 1889-97 are too high. The retired operatives are included in the census returns of 1901, upon which the rates for 1898-'05 are based.

That the Cotton Cloth Factories Acts of 1889 and 1897, now incorporated in the Factory and Workshops Act (1901), have been extremely beneficial, seems to be clearly demonstrated by the mortality returns of Blackburn. This legislation has affected Blackburn in a very peculiar manner as 382 of the 870 humid cotton factories of the United Kingdom were in the Blackburn district according to the 1903 returns. The Factory Inspector is emphatic in his statements of the improvements effected in the factories as the result of legislation beginning with 1889, but particularly since 1898. Numerous tests have shown that the respiratory impurity of the air in artificially moistened weaving sheds has been reduced on the average 50 per cent. and in several instances about 70 per cent. As this requirement for better ventilation alone affects upwards of 16,000 employees in Blackburn, its importance is readily seen. The following statement by Mr. W. Williams, H. M. Factory Inspector, made in 1901, is of interest in this connection. "Formerly (previous to 1898) it was the practice, during a considerable portion of the year, to exclude, as far as possible, fresh air from cotton weaving sheds on the ground that air 'unconditioned' (that is, not moistened or warmed) would be detrimental to the process of weaving. Now, owing to some extent to various improvements in the means of ventilating and 'conditioning' sheds, it is found possible to maintain a considerable flow of fresh air, not merely without injury, but in many cases even with positive advantage to the process, and there are sheds in Lancashire in which the operatives are supplied with fresh air to an amount equal to fully 4,000 cubic feet per head per hour."

The violations of the law are still relatively numerous, and as recently as 1903 569 instances of excessive humidity in cotton weaving sheds were reported. The leading manufacturers, however, are gradually awakening to the fact that the prevention of sickness among their employees is a real economic gain. Some of the larger employers have gone much farther in the direction of sanitary improvements than the law requires. The managers in these factories state that the improvements have not only reduced sickness but have improved the output as well.

In his report for 1900, the Inspector of Cotton Factories stated that "Experience shows that improved health conditions almost invariably lead to better work, and, looking at the matter purely from a commercial point of view, justification can generally be found for expenditure which leads to greater vigor on the part of workers." . . . "Opposition to the sanitary improvements required by law is, I think, becoming more and more discredited by the leading employers. Judging from the observations of managers and others there has already been a marked reduction in sickness in many of the sheds in which improved ventilating arrangements have been installed, and it is fair to assume that the full effects of fresher air have not yet had time to show themselves."

Although the larger portion of the legal requirements have thus far been directed to the improvement of conditions in the weaving sheds, some of the measures affect directly other parts of the mill, and all are reflected with more or less beneficial effect upon the other departments. With the introduction of one improvement others have been suggested, and while ventilation has thus far occupied most attention, temperature, humidity, cloak rooms, sanitary conveniences, etc., have all been given more or less consideration. In 1899 the Medical Officer of Health of Blackburn reported that "The health conditions under which cotton operatives work are improving rapidly." The Factory Inspector reported in 1904 that "considerable attention is being paid to the question of ventilating and humidifying spinning mills, and in some instances very great improvements have been effected."

Another factor of some importance is the gradual replacement of the old-fashioned method of gas lighting either by the installation of more modern burners, or by the substitution of electricity for gas. This means purer air in the various departments, especially in winter.

Much yet remains to be done, because many improvements are still readily possible, in the cotton mills of Blackburn, and England generally. The air in many of the rooms, not specifically covered by the Acts of 1889 and 1897, particularly in the spinning rooms, is still badly vitiated, as the reports of the Inspectors clearly show, but a large beginning has been made in the general hygienic and sanitary improvement of conditions under which cotton-mill operators labor, and the effect is already so marked as to be noticeable in the improved appearance of the workers, in their improved capacity, in the reduction of sickness and as here shown in the lower general mortality, and also in the lessened liability to consumption and respiratory diseases. It is fair to assume that the employers of their own volition will do still more than they have already done, or than the law requires, to make the conditions of work life as healthful and pleasant as may be readily possible.

TABLE VII

COMPARATIVE MORTALITY OF MALE AND FEMALE WEAVERS.

Blackburn, Eng., 1889-1905.

(RATES PER 1,000 EMPLOYEES OF SPECIFIED AGES.)

AGES	MALES		FEMALES	
	1889-'95	1896-'05	1889-'95	1896-'05
15–24.....	6.1	3.9	3.3	2.8
25–34.....	6.6	5.1	5.6	3.9
35–44.....	13.3	9.1	9.4	7.0
45–54.....	18.6	19.4	8.6	9.0
55–64.....	71.6	39.4	27.4	26.0
65 and over...	196.3	155.4	145.8	52.3

Table VII presents the comparative mortality of

weavers for the two periods 1889-1895 and 1896-1905, with distinction of sex. The rates are presented as found in the reports of the Medical Officer of Health for 1895 and 1905.

The above table shows a marked decline in the mortality of both male and female weavers except at ages 45 to 54, where there was a slight increase. This may be the effect of the lengthening of life at the younger ages. Those who formerly would have died at ages 35 to 44, may conceivably have lived a few years longer under improved conditions, only to die at ages 45 to 54, as the result of constitutions impaired beyond full recovery by the conditions previous to 1898 or even 1889. Another fact of significance is the lower mortality of female weavers at all ages. The Medical Officer of Health thinks this may be explained in part by the fact that female operatives are not as likely to be fully reported by the registrars as male operatives, particularly if the operatives are wives. It would be extremely interesting and perhaps suggestive if comparisons by sex were possible in the other branches of the cotton industry and by principal causes of death.

In conclusion we may say that the mortality returns of Blackburn deserve fuller notice in this country than they have thus far obtained. There are numerous localities in the United States where industries more or less inimical to health and longevity are centered. If the local health authorities of such trade communities were to profit by this example, their efforts would undoubtedly ultimately conduce to the benefit of both employers and employees, and therefore to the public generally.

THE PUERPERAL TYPES OF SEPSIS.*

By WILLIAM S. STONE. M.D.,

NEW YORK.

INSTRUCTOR IN GYNECOLOGY, COLUMBIA UNIVERSITY

THE discussion of the puerperal types of sepsis in connection with those seen in general medicine and surgery offers some advantages over the ordinary custom of considering them as peculiar to the puerperal state. In such a discussion as is proposed to-night, a comparison of all the different types ought to be carried along such lines as will simplify their classification.

Before taking up in detail the types seen in the puerperium, it is important to present a few facts regarding their special relations, as, differing from general surgical sepsis, the morbidity and mortality in private practice is just as high to-day as when Holmes and Semmelweis first taught us it was largely a preventable disease. The causes for this disappointing fact are related to both the attendant and the patient.

Such as relate to the attendant do not properly concern us at this time, but no opportunity should be lost of mentioning the following conditions: First, every beginner in medicine practises obstetrics, except those who are best fitted for such work, namely, the general surgeons, who rarely direct their attention to this part of the anatomy until a tumor or a prospective hysterectomy first arouses in them an appreciation of the opportunity to begin their surgical career. Secondly, and consequent upon the first condition, we are confronted with the general lack of ability to apply the principles of surgical cleanliness to obstetrics due largely to the confusion incident to the details required in the use of numerous unnecessary and harmful chemical poisons. Thirdly, the lack of preparation and of assistants for the performance of obstetrical operations makes good technique impossible.

As regards the patient and her pelvic organs, a few preliminary considerations are necessary for a correct appreciation of the regular types. The obstetrical wound is always under conditions that are incomparable to those treated by the general surgeon. To the marked congestion and increased size of the blood-vessels, always favorable for the spread of infection, there is added an excessive development of the lymphatics which Schick[1] in Leopold's clinic has recently demonstrated to be present even in the decidua, especially in the spongy layer near its juncture with the compact layer where the natural line of cleavage occurs when the uterine contents are expelled. To offset these unfavorable conditions, it may be rightfully argued that the increased metabolic activity of pregnancy should offer distinct advantages in the greater ability to eliminate poisons that may be accidentally introduced. Recent study of pregnancy, however, has shown that pathological disturbances in this metabolism are very common, and undoubtedly often furnish favorable soil for the occurrence of infection. Of 27 fatal cases of eclampsia, for example, reported by Schreiber[2] in Chrobak's clinic, 7 died from sepsis.

The gonococcus is such a frequent inhabitant of the female genitals that a knowledge of its relations in the puerperium is a preliminary essential to the consideration of the regular types. We find that it spreads in the same way as under other conditions, namely, by direct continuity of mucous membrane, the puerperal state simply furnishing conditions that are more favorable for its rapid spread, the result of which is the frequent occurrence of salpingitis. While its clinical manifestations are usually those of a mild toxemia, cases with a fatal termination are occasionally reported. A fact of the greatest importance is that this infection is practically the only one that permanently disables the pelvic organs, being practically the only cause for a chronic salpingitis, particularly that form designated as pyosalpinx. Whether the gonococcus furnishes favorable soil for the growth of other bacteria is a question not yet decided. Conclusions from the laboratory would lead us to believe that it does not. Its presence in conjunction with a severe form of streptococcus infection has been reported by the writer in a previous paper.

The relations of the colon bacillus are important.

*Read before the Section on General Medicine of the New York Academy of Medicine, April 17, 1906.

being the active agent in not a few fatal cases. Apart from its introduction from without by reason of the proximity of the anus to the external genitals, it probably has at times the same internal relations to puerperal infection that it has to appendicitis or cholicystitis. The type from this agent is usually that of an acute general peritonitis.

It can no longer be doubted that puerperal infection may be the result of the transference through the blood from foci in distant parts of the body. A very recent paper by Hallendall,[3] in Doederlein's clinic, shows that the contents of the intact amniotic sac can be infected in this way.

Finally, an important factor that must be included is the normal bacterial relations of the genital organs. The laboratory has led us through a wilderness of positives and negatives, the present conclusions from which are that, at least occasionally, the genital organs contain streptococci which the skilled bacteriologist cannot differentiate in any way from the streptococci known to be actively pathogenic. The doctrine of autoinfection must then be maintained to account for a very few cases, in which the conditions enumerated above may furnish some excuse.

While bacteriology has been of the greatest value in definitely showing that almost all of the severe puerperal infections are due to the introduction from without of the streptococcus, or much less frequently of the staphylococcus, it is of little practical value at the present time in diagnosis and treatment. Pathological anatomy, however, is of the greatest assistance, and if sufficiently studied, will accurately guide us to definite clinical types, which are comparable to those seen in general medicine and surgery.

They are best divided into the toxemias and general infections.

As toxemias are included (1) those the result of absorption of the putrefactive products of saprophytic bacteria, and (2) those the result of absorption of the products of pathogenic bacteria.

Toxemia from putrefactive changes represent, fortunately, the largest number of cases of fever in the puerperium. The fever may be high or low, usually first appearing in the latter part of the first week, frequently in the second week, rarely in the first few days; ordinarily lasting three or four days, and accompanied by a foul discharge, due to the retention of gestation products, blood clots, and lochia. It is the type that always gets well with or without treatment. If not treated, it is a frequent cause of subinvolution and uterine displacement; if treated without proper aseptic precautions, it is a frequent cause of serious general infection. A dose of castor oil, by clearing out the bowels and allowing the uterus to contract and assume its normal position, is often very efficient and a much safer therapeutic agent than an intrauterine douche nozzle or curette. This type is closely simulated by a gonococcus endometritis, and, if the latter be present, a curettage will almost surely be followed by a salpingitis.

The toxemias from products of pathogenic bacteria are very frequent. They may, perhaps, be better designated as toxemias from local infection; and even this may be objectionable, as in some instances bacteria may be present in the blood. They are not as a rule, however, and it is important to distinguish them clinically from the types to be described later. They are comparable to the cases of appendicitis that remain localized with or without abscess formation, and are characterized by the presence of an infected wound of the perineum, vagina, cervix, or placental site, or by the presence of a cellulitis which may or may not terminate in an abscess. Fever, preceded or not by a chill, beginning usually in the latter part of the first week, is high. The pulse is rapid, full, and strong. Pelvic pain may be severe, depending upon the character of the lesion. The presence of an infected wound in the lower genitals, of an abnormal discharge, if situated at the placental site, or a hard tumor if a cellulitis is present, with an entire absence of signs of peritoneal irritation, makes the diagnosis and even the prognosis practically certain, as all cases of this type get well, even if neglected. If an abscess forms and is not opened, it will follow along the cellular tissue and eventually open above Poupart's ligament, or the crest of the ilium or rupture into the vagina, bladder, or rectum. Many of these cases are severely sick for weeks and months if improperly treated at the beginning of the disease. It is the type in which unguentum Credè, various sera, and intravenous infusions have worked their apparent cures. An ice-bag, cleansing of the wounds with salt solution, prompt incision and drainage of abscesses, combined with proper hygienic and dietetic treatment, are, however, more efficient. This type not only recovers from the acute illness, but the lesions in the pelvis completely disappear, unless a gonococcus infection causes a salpingitis, either in the form of thickened tubes that are adherent in the posterior cul-de-sac to a retroverted uterus, or, as a pyosalpinx, finally renders them chronic invalids. An endosalpingitis, in other words, is not a lesion unless the gonococcus is present. If a laparotomy be performed through an error of judgment, the tubes will be found buried in an exudate upon the posterior surface of the thickened broad ligament. Their walls will be thickened from edema, but not containing pus, except, perhaps, a little near their outer ends. Removal of the tubes will be followed by recovery just the same as it would if the operation had not been performed. The subsequent course of these cases is interesting. Six months or a year afterward they will still be found trying to escape from the efforts of some surgeon to relieve them of a slowly disappearing exudate, or of an ovary enlarged from congestion that is often kept up by too protracted local treatment. Such cases more properly belong to the medical adviser. They have headaches, irregular and intermittent heart, backache, and are extremely nervous, which, with proper general treatment, eventually disappear. All of the other types belong to the general infections, which include three general varieties:

(1) The type commonly called phlegmasia alba dolens, usually appearing first in the second or third week, or even later, is due to the spread of the infection through hypogastric and external iliac veins into the femoral, causing a thrombo-phlebitis. Its clinical cause is so well understood that it need not detain us at this time.

(2) The types, generally known as septicemia, pyemia, or septicopyemia, designated by Boldt as acute and chronic bacteriemia, is the form of general sepsis most often seen by the writer, although in the report of the pathological findings of fatal cases at Sloane, recently reported by Dorman, the peritoneal type was the most frequent. They usually begin early, but, if late, almost invariably terminate as pyemia. The clinical course is so well known that I will only emphasize some of the more important points. From a practical obstetric standpoint the chief characteristic of this type is the entire absence of physical signs in the pelvis, so that many attendants still persist, especially if symptoms begin late, in ascribing them to some other cause. It is

literally a blood poisoning from the beginning, the veins being filled with bacteria, and septic thrombi may be present in all parts of the body. It is the form of the disease in which all of the therapeutic measures apparently so efficacious in the second type utterly fail; the type in which intrauterine treatment is not only a source of torment, but is also harmful; the kind in which a hysterectomy, to be successful, would have to be performed before symptoms appeared. The anatomical findings in the pelvis depend upon the duration of the disease. If the duration has been short a grumous focus may be seen at the placental site; the blood-vessels in the uterine wall and broad ligaments may be dilated, and pus may be seen oozing from the cut section. If of long duration there may be no gross appearances, the uterus even being fairly well involuted. This type is best treated medically, it being less of a surgical disease than typhoid fever. Occasionally a case of this sort recovers even when streptococci have been demonstrated to be present in the general circulation. It has occurred to the writer that baths might be used in this type of case in the same way that they are used in typhoid fever. The gonococcus occasionally follows this type, causing endocarditis and septic emboli.

(3) The peritoneal type, almost invariably fatal under the present treatment, is the one that has always most interested the writer, because it has seemed that a close study of the pathological findings would show that surgical measures might be of value. These cases seem to be analogous to the rapid and severe cases of appendicitis. They invariably begin early in the puerperium, often within a few hours after labor has terminated. There are two varieties—one, perhaps best called peritoneal sepsis, in which the peritoneum is not reddened; it may even look paler than normal. Few fibrinous flakes are seen even in the region of the pelvis. There is, however a considerable quantity of thin seropurulent fluid, which may be only slightly turbid. The pelvic organs show only a dilatation of the vessels, especially the lymphatics, which microscopically may be found to contain pus. All of the classical symptoms of peritonitis rapidly appear, and the patient succumbs, apparently overwhelmed by some intense poison. The other variety, less rapid in its course, offers an opportunity, if seen early by the consultant, to better watch the course, and possibly apply some effective surgical measures. They may be confused at first with some of the varieties described under the toxemias from local infection, but the signs of peritoneal irritation are soon manifested by the character of the temperature and pulse, and by the local signs—rigidity, local pain, and tenderness, which do not rapidly yield to the application of the ice-bag. Even if the infection has become general, opening the abdomen and washing out the peritoneal cavity seems to be indicated just as much as with a general peritonitis from appendicitis. The pathological anatomy, as the writer has found it in these cases, justifies such conclusions. The abdomen will be found to be filled with a large quantity of yellow pus and a fibrinous exudate is seen everywhere, especially in the region of the pelvis, near the ovaries and outer ends of the tubes, which are swollen and frequently contain pus in their outer third. Miliary abscesses may be present in the uterine wall. The vessels, especially the lymphatics, may contain pus which in the broad ligaments may be seen as channels of pus running upward and outward to the region of the ovaries. These cases are the only kind in which a hysterectomy with the removal of as much of the broad ligaments as possible is indicated. The peritoneal form also represents the type which the severe form of gonococcus infection usually assumes.

A STUDY OF SEVENTY CASES OF BRAIN TUMOR.*

By ARTHUR CONKLIN BRUSH, M.D.,

BROOKLYN, N. Y.

NEUROLOGIST TO THE KINGS COUNTY, WILLIAMSBURG, AND BROOKLYN EYE AND EAR HOSPITALS

The study of the interesting subject of brain tumors is one which at the present time is attracting medical investigation, as shown by the frequently reported histories of individual cases. It is evident that, however valuable these histories may be in themselves, it is only by collecting the facts furnished by a large number of cases that we can form a substantial basis for a study of the problems arising in the various questions at issue in such cases; and I have the pleasure to lay before you to-night the facts furnished by seventy cases which have come under my care in the Kings County and Brooklyn Eye and Ear Hospitals, in their relation to the various general facts, which medical science has established concerning these neoplasms. Tumors of the brain are unquestionably one of the common diseases with which both the neurologist and general practitioner have to deal, and from the increasing frequency with which the diagnosis of this condition is made, it is a fair assumption that these tumors are, like similar growths in other parts of the body, becoming more frequent. But, on the other hand, it must be admitted that, as in other conditions, this increase is more apparent than real, from the fact that the advancement in medical science has rendered us more competent to diagnose the nature of the disease from which the patient is suffering. That tumors of the brain occur at all ages is supported by the facts furnished by my cases, as the extreme limits of age in them was six months and seventy-two years. Viewed by decades the frequency of occurrence was: in the first decade nine cases, in the second ten, in the third thirteen, in the fourth eighteen, in the fifth eleven, in the sixth six, in the seventh two, and in the eighth one. The ages of my cases then support the general fact that these growths are most common between twenty and fifty, less common between birth and twenty, and least common after fifty. This greater frequency during middle life is in part due to the greater frequency of the occurrence of syphilitic tumors during that period as one of the manifestations of active syphilis. In early and late life syphilitic infection is much less common than during the period mentioned; and the fact that syphilitic cerebral tumors are never hereditary, according to Starr, explains the rarity of syphilitic tumors in children.

The fact stated by all medical writers that brain tumors are more common in males than in females is well supported by the evidence furnished by my cases, as forty-one occurred in males and twenty-nine in females.

*Read before the Medical Association of the Greater City of New York, May 14, 1906.

As to the real cause for the occurrence of most of the tumors found in the brain, medical science is as ignorant to-day as it is regarding the etiology of growths in other parts of the body. This fact is supported by the evidence furnished by my cases, as fifty-three of them occurred without known cause. In only one class of tumors can we say with certainty as to the real cause; that is, those due to bacterial or parasitic infection. From a study of these growths, however, it seems probable from the facts in evidence that some of the other forms may also be due to the presence of organisms. Of my own cases five were shown to be tuberculous and six occurred during active syphilis, and recovered under specific treatment. It must not, however, be assumed as a fact that, because a brain tumor improves under such treatment, it is necessarily syphilitic, for it is a well-founded fact that other forms of brain tumor, especially sarcoma, may at times be favorably influenced by the administration of potassium iodide. Two others were also shown to be specific at the autopsy at operation. Heredity is claimed by some as a producing cause for brain tumor, and in my own cases one patient had a father who suffered from cerebral carcinoma, and another a sister who died from a brain tumor. The number of such cases is, however, so small that from the facts in evidence the writer is inclined to believe that such a history is a coincidence, or only an evidence of some physical predisposition which renders the patient susceptible to the action of some other cause.

Injuries to the head are assigned by medical writers as one of the causes for cerebral tumors, but upon examination this theory is found to rest upon no substantial basis of fact, for it appears that no one has been able to show the methods by which a trauma produced such a result, that the vast majority of brain tumors occur without such a producing cause, that the vast majority of head injuries are not followed by such tumors, one only being claimed in three thousand cases of head injury in the writer's experience, and that all that can be claimed at the present time in support of this theory is that the injury called attention to or aggravated the course of a preexisting growth. This opinion is supported by Starr, who points out the fact that tumors, especially glioma, may develop symptoms suddenly after a blow from the occurrence of hemorrhage suddenly increasing its pressure effects, as was the case in one of the writer's cases. Three other cases in which trauma was claimed as a cause, and in which the growth developed slowly after an injury to the head, have come under my care. One was a large tuberculous cyst, occupying nearly the entire cerebral hemisphere, and could not have occurred in the short time which elapsed between the injury and the death of the patient. The second was found to be well developed one month after the injury, and at the autopsy was shown to be secondary to an unsuspected pulmonary cancer. In the third, a period of seven years elapsed without connecting symptoms before the development of the growth. The situation is further complicated by the well-established fact that a localized meningitis may at times present a clinical picture indistinguishable from cerebral tumor.

The only fact, then, that can be claimed to be proven in this case at the present time is that a cerebral injury may aggravate the growth of a tumor of the brain.

As the value of medical science depends entirely upon its power to relieve human suffering, it is evident that the nature of the disease should be recognized as early as possible, and before irreparable damage is done. Although it is often easy enough to diagnose a brain tumor in cases in which the clinical picture is fully developed, the early symptoms, and often the whole course of the disease, may be such as to make the diagnosis difficult or impossible. In the early stages of the development of a tumor we often find its symptoms simulating severe anemia, chronic nephritis, lead poisoning, and even locomotor ataxia; while in the more developed cases the picture may be that of cerebral hemorrhage, cerebral abscess, or tuberculous meningitis; and it is not uncommon to find tumors giving the clinical picture of general paresis, or even hysteria. The early diagnosis of brain tumors, as in other conditions, is often not made from the fact that the patient pays but little attention to the early symptoms, and does not seek relief until the appearance of some disabling condition.

As the diagnosis of a brain tumor can only be made by the combination and the order of the development of the symptoms (Starr), we find the problem then complicated by the fact that the early symptoms are often subjective and frequently referred to other conditions; that the earliest manifestations may be monosymptomatic and a correct diagnosis for a time impossible; that tumors, especially tuberculous, may give no symptoms whatever, even in situations where such tumors should do so, and then do so suddenly from the occurrence of hemorrhage in or about the tumor; and that brain tumors may simulate other cerebral diseases. This seeming anomaly of the absence of symptoms is explained by the fact that the brain can accommodate itself to pressure if produced gradually, and that tumors which grow slowly, and do not infiltrate, may thus reach a considerable size before definite symptoms occur.

Assuming, then, these sources of error, it is unfortunate that the slow and regular development of headache, vertigo, projectile vomiting, nausea, general convulsions, mental apathy, optic neuritis followed by loss of vision, insomnia, attacks of syncope, and changes in the pulse as general symptoms, with localized spasms, monoplegias, hemiplegia, anesthesia of one or more limbs; changes in the reflexes, pupils, and visual fields, ataxia and paralysis of the cranial nerves, to guide us as to the location of the growth, do not occur in the majority of the cases. This fact is well supported by the evidence furnished by my cases, as such a history is to be found in but eighteen of them. In these cases the average time for the symptoms to attain such a degree of development for the patients to seek medical aid varied from two months to ten years; but only three were of over three years' duration, these being of four, five, and ten years' standing. Of the remaining, five had existed two years, four one year, and six from three to eight months. That tumors of the brain are, as a rule, slow in their development, is supported by the evidence furnished by my cases, as such was the history in sixty-two. In the remaining eight the duration was from two to eight weeks. Four of these were undoubtedly syphilitic, and this rapid development supports the well-established law concerning the development of syphilitic cerebral neoplasms.

The fact of the importance of early recognition of these tumors having been established, the study of the initial symptoms becomes imperative. The fact that the mode of invasion may differ in the different cases is well supported by my cases.

Convulsive seizures was the most prominent early symptom in twenty of my cases. The form of the seizure naturally divides them into three classes: In the first class, the convulsions resembled those of the general epileptic or grand-mal type, and of all

the modes of development of brain tumors this clinical picture has been the commonest source of error in the early diagnosis. For, as is well established, both by the experience of others and the evidence presented by my cases, these convulsions may exist for some years before the development of the other symptoms of brain tumor; and even when headache, vertigo, and loss of vision develop, their significance is not always recognized. Twelve of these twenty cases were of this type, and their duration, before the real nature of the disease was recognized, varied from four months to ten years. It is to be noted that two of these cases differed from the classical picture of idiopathic epilepsy in the brief duration of the coma; that in three an aura consisting of local tonic spasm occurred, and in five a local paresthesia.

Cases of the second class, in which the symptoms are of the petit-mal type, are much less common, as is also shown by my cases, for only two were of this kind, and in both the development of other symptoms led to an earlier recognition of the existence of a tumor than in the grand-mal type, for their duration was only two and six months.

The third class is that in which the attacks consist of localized spasm without loss of consciousness, this spasm gradually increasing in extent; and if it thus becomes general, it is accompanied by loss of consciousness. This Jacksonian form was found in six of my cases. In these cases, such positive evidence of local cortical disease, combined with the fact that the disease is extending, should cause an early recognition of the nature of the disease. This is fortunate, as in no class of brain tumors is surgical relief so certain. The duration in my cases varied from three months to six years, three lasting less than one year.

Next to convulsive disorders defective vision was the most common early symptom for which the patient sought relief, and from the established fact that neuroretinitis occurs in 80 per cent. of all brain tumors, one would suppose that it would be even a more common early symptom; but it is also a well-established fact that a high degree of such neuroretinitis may occur before the patient notices the visual defect. The actual loss of vision is frequently confined to some one part of one or both retinæ. With this loss of vision in my cases there was also associated the usual symptoms of a brain tumor whose significance was not recognized. The duration of the disease in my cases varied from ten days to three years, eight being of less than three months' duration. Of the nine cases the development of the loss of vision was sudden in four, probably due to the occurrence of hemorrhage.

Severe headache, associated with nausea, vomiting, and vertigo was the early clinical picture in four cases for a period varying from three months to one year, and during this period the real nature of the disease was a matter of doubt.

In three cases an ataxic gait, with increased knee-jerks and vertigo, existed for a period of three years before the development of other symptoms. In three cases the first symptom was the slow development of a hemiplegia during a period of from one to three years. In two cases a subjective vertigo existed alone for a period of three and eight months.

In four of my cases the real nature of the disease was not recognized during life, and was only discovered at the autopsy, the diagnosis having been paretic dementia, chronic dementia, and two large tuberculous tumors gave the history and clinical picture of major hysteria.

Three other cases not included in this list were diagnosed as brain tumor, but were found on operation to be cases of localized meningitis.

The advancement in the localization of cerebral disease has been so great that at the present time we can speak with reasonable probability as to the location of the disease, but not with absolute certainty, for reasons already in evidence, and from the fact that tumors may cause misleading symptoms by pressure on adjacent tracts or by disturbing the circulation. In my own cases six were not localized, six were considered as cerebellar, five in or about the pons, seventeen in the motor cortical region, six as tumors of the base, seven of the basilar ganglia, and eighteen as subcortical. In four the localization was found to be incorrect, either at the autopsy or on surgical operation.

The nature of a brain tumor is, during life, unless the case comes to operation, merely speculative. It is a reasonable probability in patients suffering from a malignant tumor in some other part of the body, that a subsequent brain tumor is of the same nature, and also, when the patients are suffering from tuberculous deposits in other parts, that it is tuberculous—but in my own cases such evidence was absent. This supports the fact that tuberculous brain tumors are, as a rule, primary. The existence of a syphilitic infection is, as a rule, competent evidence as to the nature of the tumor, but it is not conclusive, as a syphilitic may suffer from tumors of other kinds, as was the fact in two of my cases.

In my own cases the nature of the tumor was determined in fifty-two. This list includes eleven syphilitic patients who recovered under specific treatment. Of the others nine were glioma, fourteen sarcoma, seven tuberculous, four cystic, one angioma, and one psammoma.

The results obtained by treatment in my cases may be tabulated as follows: fourteen recovered under medicinal treatment, nineteen were improved by surgical means, thirteen died, twenty-six passed from observation as unimproved, and eight are still under observation. The only drugs which are known to influence favorably the growth of a tumor are potassium iodide, mercury, and arsenic. The results obtained in my cases are as follows:

Under the administration of potassium iodide in from ten to fifteen-grain doses, seven made a complete recovery in from two to four months. In four of these cases there was an old and obscure syphilitic history. In the others no such history was in evidence. These are classed as syphilitic, but for reasons already in evidence the fact cannot be claimed as proven. Six of my patients recovered in from two to three months under the use of mercury, followed by the iodide. In all, there was evidence of recent syphilis. In my own experience, no form of administration of mercury has given such good results as the mercurial inunction. One case improved markedly under the use of Fowler's solution, and passed from under observation after a period of six months.

Tumors of the brain which do not rapidly show some improvement from medicinal treatment, are, if located in accessible regions, proper subjects for surgical interference, for the reason that death is the usual termination. Operation, however, should not be too hastily advised, nor should too brilliant results be held out, for the reason that we cannot repair the actual damage done by the tumor, and the necessary damage done in its removal may cause new or increased paralytic symptoms. It is also true, however, that we may at times improve or cure such paralytic conditions when they are due to pressure by the growth on adjacent parts. It is also true, as in cerebral hemorrhage, some improvement may occur in the paralyzed parts from the functions of the injured cortex being supplied by other parts of

the cortex. The patient, then, and his friends, should clearly understand that the operation is for the purpose of arresting the course of the disease, rather than a cure for all his symptoms.

In the nineteen cases in which surgical procedure was undertaken, the tumor was found to have been correctly localized in eighteen. In the one case in which the tumor was found to be incorrectly localized, the symptoms were those usually found in the lateral lobes of the cerebellum, such as marked ataxia, marked optic neuritis, vertigo, and a well-marked tendency to fall to one side. On the autopsy the growth was found in the frontal lobe. This case supports the fact already in evidence that tumors may give rise to symptoms referable to other parts of the brain, either by pressure on adjacent tracts or by disturbances of the circulation.

In two cases the tumor was found to be irremovable, because of its size, indefinite outline, and malignant nature. The remaining sixteen cases may be briefly summed up as follows:

Case I. Subcortical sarcoma of the temporal region. Eighteen months' duration. General symptoms cured. Vision improved. Hemiplegia unimproved.

Case II. Subcortical cerebellar glioma. Two years' duration. General symptoms much improved. Optic neuritis and loss of vision improved. Ataxia unimproved.

Case III. Cortical tuberculous tumor of the Rolandic region. One year's duration. Localized convulsive seizures cured, but the operation was followed by paralysis of the arm, which remained permanent in the extensors of the hand.

Case IV. Cortical sarcoma of the parietal lobe. Three years' duration. General symptoms, optic neuritis, and loss of vision improved. Jacksonian epilepsy cured; the hemiplegia was at first much increased, but afterwards improved.

Case V. Meningeal fibrosarcoma of the Rolandic region. Six years' duration. Tremor of the arm with loss of power cured.

Case VI. Subcortical syphiloma of the occipital lobe. Two years' duration. General symptoms much improved, but the loss of vision and ataxia remained unchanged.

Case VII. Meningeal sarcoma of the Rolandic region. Two years' duration. General symptoms and local convulsive seizures cured, but the hemiplegia only slightly improved.

Case VIII. Meningeal tumor of unknown nature of the Rolandic region. Two years' duration. Tumor not removed, but all its vessels ligated. Jacksonian epilepsy cured; the hemiplegia was at first increased, but subsequently improved.

Case IX. Meningeal, tumor of unknown nature of the Rolandic region. Three years' duration. Tumor not removed, but all its vessels ligated. Jacksonian epilepsy of the arm cured; the loss of power in that arm was for a time much increased, but finally recovered.

Case X. Meningeal tuberculous tumor of the Rolandic region. One year's duration. General symptoms and local spasms cured, but the hemiplegia was permanently increased.

Case XI. Subcortical glioma of the parietal lobe. Two years' duration. General symptoms improved, but the loss of vision and hemiplegia remained unchanged.

Case XII. Subcortical sarcoma of the occipital lobe. Two years' duration. General symptoms improved, but the optic neuritis and loss of vision remained unchanged.

Case XIII. Meningeal psammoma of the Rolandic region. Six years' duration. Local convulsive seizures of the arm cured, but permanent paralysis of the extensors of the forearm occurred.

Case XIV. Subcortical sarcoma of the occipital lobe. One year's duration. General symptoms improved, but the loss of vision permanently increased.

Case XV. Sarcoma of the parietal region. One year's duration. General symptoms cured. Loss of vision, hemiplegia, and ataxia improved.

Case XVI. Subcortical sarcoma of the parietal region. One year's duration. General symptoms, except mental condition, cured. Mental apathy improved. Loss of vision permanent. The established facts, then, in the surgical aspect of brain tumors, would seem to be at the present time that no case should be subjected to operation until it had failed to improve after a month of treatment by the iodides or mercury; that the non-malignant nature of the tumor should be established by its slow growth; that we should be able clearly to localize its position in a surgically accessible region; that it should be of moderate size and have clearly defined outlines; that in subcortical tumors a moderate incision of the cortex does not cause any serious consequences, and that the best results are to be obtained in early cases which show but little evidence of brain destruction.

AIR DILATATION IN THE TREATMENT OF CHRONIC CONSTIPATION.*

By LOUIS J. HIRSCHMAN, M.D.,

DETROIT, MICH.

CLINICAL PROFESSOR OF PROCTOLOGY, DETROIT COLLEGE OF MEDICINE
PROCTOLOGIST TO HARPER HOSPITAL. GYNECOLOGIST TO
GERMAN POLYCLINIC; FELLOW OF THE AMERICAN
PROCTOLOGIC SOCIETY, ETC.

In presenting a paper on any phase of treatment of constipation before an audience composed of general practitioners, the first point which one would wish to emphasize would be the question of the diagnosis of constipation from obstipation, and one would dwell at some length upon the importance of making a rectal examination in all cases which present constipation as a symptom. However, before an audience composed of proctologists, it would be superfluous to mention anything regarding the importance of making a differential diagnosis between these two conditions.

That chronic constipation is probably the most prevalent disease condition existing to-day, I think cannot be doubted. This is shown by the fact that no matter where one goes glaring advertisements of all manner and kinds of aperient waters and cathartics are flaunted in one's face, the bill-boards, the street cars, the newspapers, the magazines, all are utilized by the venders of these various cathartics in proclaiming their wares to the general public. Every day the detail man brings to our office some new cathartic brought out by a reputable pharmaceutical house, which is "absolutely an ideal cathartic and the one for which we have long been looking."

Proctologists, however, realize that one is no more justified in treating chronic constipation with cathartic drugs than is one justified in treating chronic appendicitis by a chronic drugging.

It is not necessary to recall to this body that the most important factor in stimulating physiological peristalsis is distention of the gut. From the time that the stomach contents pass through the pylorus into the duodenum several factors are at work to produce physiological distention of the

*Read before the American Proctologic Society, Boston, Mass., June 6, 1906.

gut. The chemical reaction caused by the action of the alkaline intestinal secretions upon the acid stomach contents as they are poured into the duodenum causes an irritation or stimulation of the mucous coat of the gut, which sends down a wave of peristalsis. The gases which are formed by this reaction of alkali upon acid distend the gut mechanically and stimulate contraction, and the solid and indigestible portions of the food which have passed through into the gut, also by their bulk cause distention and consequent contraction.

As long as we have all of the physiological stimulants to peristalsis in good working order, just so long will we have excretion carried on in a proper manner. If, however, we have all of these factors at work, and a properly bulky stool is brought down to the colon and into the sigmoid, and if at the proper time the sigmoid endeavors to expel the feces through the rectum and anus, and the tightly contracted sphincter offers more

Fig. 1.

Fig. 2.

resistance than the expulsive effort can overcome, we shall have constipation.

If nature does her part well, and the individual, because the time or place is not convenient, represses nature's effort, soon she will tire of this interference and atony of the bowel will result, and atony of the bowel is responsible for a vast majority of cases of chronic constipation.

An atonic bowel requires more stimulation to cause it to contract than a normal bowel; although the food may be properly ingested and digested, its stimulus will not be sufficient to bring on a proper evacuation.

It is a fact, however, that in chronically constipated individuals there are usually dietetic errors and lack of proper exercise, which are contributory causes, besides the refusal to obey nature's summons; yet, in many cases where dietetic error is corrected, the proper amount of vegetable element is included in the stool, the proper amount of fluids is taken into the system, the food is properly masticated by teeth which are in good condition, gastric digestion is all that it should be, the patient takes plenty of exercise, in spite of all this he is unable to extrude a proper stool without assistance.

A stool solid enough, and of the proper shape to dilate gently the sphincter on its extrusion, is very necessary to normal health. The sphincter, as you know, is surrounded by a sympathetic plexus, and it is also well known that dilatation of the sphincter is one of the most powerful stimuli that we possess in shock. It is also a well-known fact that when the sphincter is properly dilated by a proper, normal-shaped stool, one has a sense of well-being not entirely accounted for by the simple evacuation of a loaded sigmoid. This well-being, I believe, is due to the stimulation derived from nature's dilator, a perfect stool, and we must regulate the diet so as to secure enough bulk to give a properly shaped stool for proper normal sphincteric dilatation.

A great many drugless methods of treating constipation have been offered to the profession. All kinds of electric and external massage, cannon-ball gymnastics, vibratory massage, and what not have all been tried, and, while satisfactory results have been obtained from each of them in certain cases, there still seems something to be desired in the successful treatment of chronic constipation.

The direct stimulation of the atonic sigmoid and rectum by means of mechanical dilatation has, up to the present writing, given the best results. Rubber bags, which have been introduced through the proctoscope into the sigmoid and inflated, have been used with excellent results. Tamponing the rectum and sigmoid with cotton, wool, or gauze, has by its mechanical irritation of the mucous coats of the bowel and its stimulating the normal bowel contents produced satisfactory distention with its following contraction and evacuation. The inconvenience of carrying around a tampon or inflated bag in the rectum or sigmoid for from four to six, or even twelve hours, has, however, militated somewhat against the more general use of these methods.

The writer has devised a very simple pneumatic dilator for accomplishing this distention, and wishes here to present it to the members of the Society for their inspection and criticism. The author claims no great originality for this device. It simply consists of a rubber bag with a stem, which is slipped over the distal end of a Wales bougie (No. 3-5), the Wales bougie being canaled (Fig. 1). Compressed air at a low pressure is slowly allowed to enter the bag, and distention to any desired extent is produced. By means of a cut-off valve this distention can be easily regulated. Where the compressed air apparatus is not convenient, an ordinary atomizer bulb (Fig. 2) or a small bicycle pump may be utilized.

The patient is placed in the Sims position. The bag is lubricated and deflated, is passed upward into the rectum, and through the rectum into the sigmoid to any desired height, the Wales bougie being firm enough to carry the bag up into the sigmoid, and yet being flexible, does not create any discomfort or do any injury in its passage; and it obviates the use of the proctoscope in its introduction. When the bag is in position it is slowly inflated until the patient complains of a sense of either fullness or pain, or a desire to move the bowels. The air is allowed to escape,

and after an interval of a few seconds it is again inflated to the point of tolerance. This alternate inflation and deflation is repeated about four times to the minute for a period of five minutes or so; then the bag is inflated again to the point of tolerance; the cut-off valve is disengaged and the opening in the bougie is closed with the thumb, and then, by a to-and-fro motion, the apparatus is gently and slowly withdrawn. This massages the bowel as it is withdrawn, and also gently dilates the sphincter.

This treatment is repeated daily for from five days to a week, and usually after the first or second treatment the patient will have a small unaided movement. Cathartics and enemata are, of course, strictly enjoined. Each day the patient will report a slightly larger and more satisfactory defecation. When the defecation approaches the normal, treatments are given only on alternate days. After three or four days, the interval is lengthened to two days, and then to three; and then to four; then the patient is asked to report again in five or six days. If he reports satisfactory evacuations daily he is allowed to go a week, and then, if a similar report is made, he is discharged as cured, but asked to return on the first day on which he does not have a normal stool.

If the case is properly diagnosed and instructions as to a regular time for daily evacuations and strict obedience to nature's calls are carried out by the patient, as well as the proper dietary being lived up to, the results from this method of treatment will be very gratifying.

In the author's experience, now extending over nine months, he can recall but two cases in which success was not attained. In about eighty cases, so far as he has been able to learn through subsequent inquiry, permanently good results were obtained.

604 Washington Arcade.

THE TREATMENT OF INJURIES TO THE EXTREMITIES BY MECHANOTHERAPY.

A REPORT OF CASES TREATED AT THE ROOSEVELT HOSPITAL.

By WILLIAM O. RAU, M.D.,

NEW YORK.

In our hospitals, as well as in private practice, the surgeon is often satisfied with a purely anatomical recovery of a fracture, a dislocation, or any other injury of the extremities, and he pays too little attention to the functional recovery. A patient comes to the hospital with a fracture, the best care and skill are used to secure perfect union without deformity; a radiograph is taken, the fracture is reduced, the limb put into splints. The patient occasionally gets a few minutes' massage. After a certain number of days or weeks the splints are removed, the patient discharged as cured, and he is seldom seen again by his surgeon, who never knows how soon he was able to resume his occupation, if ever. He had a perfect union and no deformities, but was he fit to go to work and earn his living? Had he obtained a complete functional recovery? Is it not a fact that this patient entered as cured in the records was far from being capable of using his limb? For weeks after being discharged he will be idle, his muscles weak and atrophied, his joints stiff. In some cases the function of the limb is never restored. Fractures of the patella, of the condyles, of the olecranon, dislocations of the elbow, are often followed by a permanent total or partial disability. The surgeon cannot be held responsible for this, because he has not at his disposal the means of treating his patient for functional as he has for anatomical recovery. But he should remember, when he discharges him, that he has fulfilled only part of his duty to his patient.

A great deal is done in France, Germany, and Switzerland by the Accident Insurance Companies to secure a rapid functional recovery of injuries. These companies have spent enormous sums to fit up their hospitals with every appliance suitable for that purpose. In doing this they realize considerable savings in compensations paid for loss of time or for permanent disability. In 1894, before the Congress of Milan, Boedicker said: "Since 1892 we have recorded a much larger proportion of complete functional recoveries of fractures. In 1888, before the use of a methodical treatment of accidents, the percentage of cases treated for twenty weeks or more was 55. Since 1892, when mechanotherapy was used, for the treatment of these cases, the percentage has fallen to 2."

The arthromotor devised by Dr. Chas. Scholder of Switzerland is an important step forward in the field of mechanotherapy. The arthromotor combines into one machine everything needed for the treatment of the extremities. It gives passive as well as active movements, and can be fitted for every joint of the extremities, it can be regulated so as to go from the shortest to a full normal movement, and so as to begin the movement at any angle. The treatment is absolutely painless, as the machine can be set so as not to go beyond the painful point. It is impossible to obtain this regularity of the passive movement by manual treatment. No matter how skilled the operator is in giving passive movements by hand, he cannot judge exactly how far he can go without giving pain. The patient instinctively contracts his muscles and interferes with the work of the operator. When the machine is used the patient soon finds out he need not fear pain, and all the muscles are relaxed. When using the machine for active movements one can measure and regulate the resistnace for any degree of muscular energy and increase it every day as fast as the muscles regain their strength. Two graduated dials indicate the amplitude and angle of the movement; by making a record of these figures the surgeon can follow day by day the improvements in the condition of his patient, and he can keep that record for future reference. With the advent of this relatively simple machine a large field is open to mechanotherapy, and we shall probably see this treatment play an important part in the management of cases of accidents.

Massage and, if possible, local application of heat, should always be resorted to in connection with the mechanical treatment. The importance of massage is too well known for me to dwell on the subject. The action and *modus operandi* of heat is, perhaps, not so well known, and it may be useful to say a few words about that part of the treatment. The object should be to subject the limb to as high a temperature as possible without danger of injury to the skin. I have tried different apparatus, some using gas, others electricity, as a means of producing heat. For the last two years I have used the Dowsing Radiant Heat apparatus exclusively, the principle of which is to use heat and light rays combined, or luminous heat, instead of dark or nonluminous heat. It consists of high-candle-power electric lamps fitted on polished reflectors, which project the heat on any part of the body. The lamps are rich in red heat

rays and yellow light rays, but exclude the violet rays, which are more or less irritating to the skin. There is no need of an enclosure, the limb is simply exposed to the rays and a temperature of from 400° to 500° Fahrenheit is easily borne. When using a nonluminous appliance one heats the limb by contact. That is, the air is heated, and this in its turn heats the skin without raising the temperature of the deeper tissues to any extent. With the luminous apparatus one does not depend on hot air but on direct application of heat and light rays to the part. It has been proved by experiments on animals that the light rays penetrate the skin, where the shorter waves of the spectrum are transformed by the resistance of the tissues into long heat waves. In that way the heat is carried to the deep-seated organs. The apparatus constructed for the treatment of the full body is used for cases of rheumatism, gout, rheumatoid arthritis, etc. For the treatment of accidents I use the local apparatus devised for the treatment of a limb only. Luminous heat rapidly increases the absorption of the exudate, improves the circulation, and has a marked sedative action. I have often found in cases of recent sprain of the ankle with intense pain, that the patient could easily bear the massage after fifteen or twenty minutes' application of luminous heat.

The cases treated in the mechanical department of the Roosevelt Hospital, from February to December, 1905, were sprains, fractures, dislocations, contusions, rupture of muscles, synovitis, adhesions, stiffness following arthritis, cellulitis, tenorrhaphy, operations on the joints, etc.; 4,005 treatments were given in eleven months. The large majority of cases treated were fractures and dislocations. We were kept so busy with those cases that it was found difficult to undertake the chronic and slower cases. The results have been very encouraging and often remarkable. As a rule the patients were sent for treatment at an early stage; we shall see later that this plays an important part in the ultimate functional recovery. Each patient reported to the surgeon who treated him about once a week and before being finally discharged. In that way the surgeon first in charge of the case had an opportunity of following closely each one of his patients from the day he was sent to the mechanical department to the day he was discharged.

Fractures.—We had 215 cases of fractures; in 130 cases a complete functional recovery was obtained, 82 were improved, 3 failures. By functional recovery I mean not only that the patient went to work immediately after being discharged, but also that he had obtained the full normal movement. The cases reported as improved only were of patients who either went to work before obtaining a complete normal movement or left before being discharged by us.

Fractures of the forearm: 137 cases; 87 recovered, 44 improved; 1,348 treatments. The treatment was begun from the 7th to the 12th day, the splints cut short from the 14th to 18th day, and removed as early as the 21st day after the accident. All cases where the treatment was begun early recovered in a remarkably short time, most of our patients doing hard work thirty and even twenty-seven days after the accident. A marked improvement was always obtained, even in cases of old standing.

Fractures of the humerus: 50 cases, of which 24 of the condyles; 25 recovered, 22 improved; 3 bad T-fractures were failures. Cases of fractures of condyles in children did well; the treatment was begun between the 10th and 20th day, and from 7 to 29 days were required for a complete functional recovery. A six months' case, a child four years old, which had only 30° of movement, obtained a full flexion and extension after 47 treatments.

Fractures of the patella: Some of our cases did remarkably well, others were almost a complete failure. When the treatment was begun early the recovery was very rapid; when it was begun late it took weeks to obtain an improvement only. A man twenty-two years old, treatment begun five weeks after operation, had 5° of passive movement, complete flexion, leg strong, goes to work after three weeks of treatment, or eight weeks after operation. On the other hand, a young woman who began ten weeks after the operation had sixty-nine treatments and obtained 25° only of flexion. It was found impossible to obtain more under anesthetics.

Fractures of the leg: Patients working as early as forty days after accident.

Pott's fractures: Treatment begun twenty-one days after accident, recovery fifty-six days after accident, splints removed six weeks after accident.

Dislocations.—In those cases the treatment should be begun early. I see no reason why the treatment should not be begun immediately for dislocation of the elbow, providing active movements are not allowed at first. Cases undertaken a day or two after the accident recovered rapidly, while old cases were slow and tedious. Dislocation of the elbow is often followed by a permanent partial disability, the extension being impaired in most cases. In all cases the flexion was obtained much quicker than the extension. From fourteen to seventy-three treatments were required for a complete recovery.

Sprains.—Massage and mechanical treatment can never be started too soon for sprains. Much has been written on the treatment of sprains by massage, and very few surgeons, I think, still adhere to the old treatment by immobilization. Very quick recoveries have been obtained by massage only. I think that with the addition of heat and passive moments by machinery the length of treatment can still be considerably reduced. The passive movements by hand are always more or less painful, while they are painless by machinery. I have seen patients beginning treatment with the arthromotor with an almost imperceptible flexion and extension of the ankle, stand, at the end of ten or fifteen minutes, an increase of 10° to 15° without discomfort. The heat is also an important factor in alleviating the pain, reducing the exudates, and improving the circulation. Patients should be instructed to walk; a compressive bandage is useful. I have never seen a case of recent sprain (by recent I mean four days or less) need more than ten treatments for a complete functional recovery. They averaged five or six days, and in some cases one treatment sufficed.

Conclusion.—In this short report I have merely given the outlines of the treatment and of the work accomplished in eleven months at the hospital. I have mentioned only cases treated at the hospital, because these cases were under the direct observation of the different surgeons of the hospital who sent them to us. We were kept very busy and a short time only could be given to each patient. If more time daily could be devoted to each case, a better record could be obtained. The general results have been very satisfactory, and we think that the treatment deserves to be given due consideration by the surgeons and to be adopted in our hospitals. We think that if it is properly given it will lessen to a great extent the period of idleness following injuries to the extremities. This is especially important in the case of workingmen, when every day of idleness means a loss of wages and a hardship for the injured man and for his family.

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, August 11, 1906.

COMMERCIALISM IN MEDICINE.

IN a thoughtful address on "The General Practitioner and the Specialist," delivered before the Massachusetts Medical Society (*Boston Medical and Surgical Journal*, July 26, 1906), Dr. John L. Hildreth brings up again the vexed question of the value of medical services, or rather the value which certain practitioners put upon their own services. He deprecates what he calls the spirit of commercialism in the practice of medicine, and says there is a feeling among some of the older practitioners that this spirit is taking a very strong hold of the whole profession. As evidence of this tendency toward commercialism, he instances the thousand-dollar fee which a New York dentist is said to have exacted of Prince Henry of Battenberg for filling a few of the illustrious visitor's teeth, and the charge of $1,000 made by a surgeon of this city for an operation for appendicitis. The two instances are not parallel, and their citation together only illustrates the futility of the discussion of this subject from a single point of view. As well almost might one compare the wages of a stone-cutter and the fee of a sculptor. The work of a dentist is one calling for knowledge, judgment, and skill of a high order, but it is in no sense comparable to that of the abdominal surgeon, upon whom rests a load of responsibility for the life of his patient, which vastly increases the value of his services. Assuming that the qualities above mentioned are the same in the two men, the circumstances render their exercise in the surgeon more difficult. It is recognized in all professions and walks of life that the greater the responsibility attached to an office, the more highly paid shall be the man who fills it. The alleged fee of the dentist might fairly be characterized as exorbitant; that of the surgeon might be thought high, but it was not exorbitant. As Dr. Hildreth says, the patient pays the surgeon, "not for the brief time spent in an operation, but for the skill and training which have been acquired by years of strenuous effort, and upon which he bases the assurance with which he gives himself to the surgeon's knife, certain that everything which science can do to relieve his suffering and save his life will be done. That sense of assurance is worth so much to the patient that he should not begrudge paying for it, provided the fee of the operating surgeon is not beyond reason."

Many other factors must enter into consideration in determining the fee question. A man of reputation is legitimately entitled to a larger fee than the surgeon who has not yet proved himself, even though the latter may regard himself, and actually may be, possessed of greater ability than his more renowned colleague. A surgeon practising in a large city, where living expenses are higher, must be paid more for his work than his country brother, who may be his superior in many ways, but who lives in a community where the scale of prices for everything is lower. Then again, there is the delicate question to be considered of the patient's means. The life of a poor man is as dear to himself and his family as that of the rich man, and may be of far greater worth to the community, yet the surgeon or the physician naturally does not and can not charge him the same fee for his services that he will the latter.

It is here that the "spirit of commercialism," we are forced to admit, sometimes shows itself. The commercially-inclined practitioner too often grades his fee upward according to the wealth of his patient, regarding the "plutocrat" as a lamb to be sheared. To quote Dr. Hildreth again, "in too many instances this fee seems to be based, as the railway magnate said of the freight charges, upon 'what the traffic will bear.'" The conscientious physician should formulate for himself a fee rate, and exact this of all his patients who expect and are able to pay the "market rates" for all they receive, whether groceries or medical services. He is not in duty called upon, except in case of emergency, to treat one who can not afford to pay his regular fee, but if he does he remits a part or all of his bill to meet the necessities of his patient. But this is a voluntary act of charity, and the practitioner has no moral right to compensate himself for the undercharge by overcharging the next millionaire who seeks his advice. He should exact of him only the regular fee which he charges for services rendered to all his well-to-do patients. It was the highwayman of old who robbed the rich to feed the poor, but in these days of organized medical charities the physician is not called upon to fill this rôle. After the death of a multimillionaire the newspapers sometimes report the filing of an excessive bill for medical services against the estate. It is these reports—rare, we are pleased to note, for the honor of the profession—which bring discredit upon our guild, and give occasion for comments upon the "rapaciousness of physicians," exposing the honorable and conscientious practitioners, who constitute the great mass of our profession, to the undeserved charge of "commercialism."

SOURCES OF ERROR IN EXAMINATIONS OF THE STOMACH CONTENTS.

IT is now some twenty years ago since Ewald and Boas first introduced the so-called "test breakfast" as a means of determining the secretory and motor functions of the stomach. Experience has fully demonstrated that this method, although simple, is the most practical for the purpose stated, and among its numerous advantages is the ready means which it affords for differ-

entiating the individual constituents of the gastric contents, both qualitatively and quantitatively. A critical inspection of the literature shows that physicians have subjected the original formula to modifications without number, which in most instances are far removed in purpose and design from the specifications laid down by Ewald and Boas, and are therefore very apt to lead to false conclusions. The test breakfast, as originally proposed, consists of a white bread roll weighing about 35 gm., together with 400 gm. of water or tea, without the addition of cream or sugar. The patient is directed to take this on an empty stomach, and an hour later the contents of the organ are syphoned out with a stomach-tube and analyzed. This is essentially the original method, but, as Boas states in a recent article written for Ewald's "Festschrift," every one of these specifications has been subjected to some change or other, so that in many respects there is little resemblance to the original procedure. Thus a common mistake arises from the fact that the precaution to give the meal on an empty stomach is not closely observed; it is simply administered before breakfast without any assurance being obtained that nothing remains in the organ from a previous meal. If this precaution be omitted the end result will, of course, be affected. It is essential that the test be preceded by the inspection of the stomach with the gastric syphon, in order to ascertain whether any residue is present. After this point has been determined the preliminary syphonage can, as a rule, be omitted with subsequent examinations.

Another source of error arises from the fact that the test meal is not given early in the morning before breakfast, as originally prescribed, but at some other more convenient time of the day. It would be possible to determine the presence of free hydrochloric acid by this means, but only a positive finding would have any value under these circumstances, and the quantitative determination of the HCl, or the presence of lactic acid and other substances, could of course not be taken into consideration. Another, and most important factor, which affects this, as well as all other methods of a similar character, is the variation in the excretion of HCl which characterizes the individual. The quantity may vary within wide limits in different patients, and this fact demonstrates quite conclusively that a single examination of the gastric contents, except in isolated cases, cannot possibly afford sufficient evidence for an absolute diagnosis.

It seems, therefore, that this well known and highly valued "test breakfast" is, like most other clinical methods, subject to certain sources of error, and is also limited in its application. Careful attention must be given to all secondary factors which may have a possible bearing on the outcome of the method, and also to every technical detail of the procedure. Notwithstanding all this, there is little doubt that the method with which the name of Ewald is closely linked will continue to be the simplest and most satisfactory diagnostic means for testing the secretory and motor functions of the stomach.

IMPURE AIR IN SHIPS.

An important chapter of naval hygiene is concerned with the contamination of the air in the holds and other closed compartments in vessels. Such contamination may be brought about by certain changes which take place in the cargoes, or it may be due to the metal hulls. These conditions are not merely of theoretical but also of great practical interest, for every year there occur a number of fatal cases of asphyxia due to the inhalation of this poisoned air. These accidents usually take place shortly after coming into harbor, and particularly in those ships which have just completed a long voyage. While on the high seas the hatches and ventilators leading to the cargo spaces are ordinarily closed, but when port is reached they are immediately opened. Sailors and others who venture into these insufficiently aired compartments are then frequently overcome, and those who attempt to rescue them are liable to meet the same fate.

It has generally been supposed that an excess of carbonic acid gas produces the fatal issue, but in an article by G. Giemsa in the *Archiv für Schiffs- und Tropen-Hygiene* for March, 1906, it is quite conclusively demonstrated that this is not the only cause. The rapidity with which death came on in most of the cases reported seemed to point rather to an insufficient quantity of oxygen in the air of these places. In order definitely to determine this point and also the possible effect of the cargo on the contamination, an elaborate series of experiments was conducted by Giemsa, who is connected with the famous school of naval medicine in Hamburg. The ordinary method of testing the quality of the air in any given locality by observing its effect on an open flame was found to be unsatisfactory and insufficient, for the latter was not extinguished until the oxygen content of the air had been reduced to from 14 to 15 per cent. and a greater proportion of oxygen than this is necessary to sustain life. It was also found that this diminution in the amount of oxygen can in many cases be traced to the character of the cargo, many kinds of which become rapid consumers of oxygen under certain conditions. Increased humidity and elevated temperature were found to favor this process.

Giemsa has found that animals make much more satisfactory test objects for the purpose of determining the lethal quality of the air in ships' holds, than the commonly employed lamp flame. He recommends that mice be lowered into the hold in small cages and the effect observed. If the contained air does not support animal life, then means must be taken to clear out the contaminated air, and this can be accomplished only by active mechanical ventilation—it is not sufficient merely to open doors and hatches. In order to overcome the oxygen-consuming properties of the cargo, receptacles containing ordinary lime may be placed in the compartments.

A study of these facts is of considerable commercial value, and they should be made a matter of common knowledge among those in charge of vessels. The dangers connected with a seafaring life are by no means limited to the time when the vessel is under way and, as will be seen from the writer's timely articles, those which are liable to occur in harbor are also to be reckoned with.

AMAUROSIS DURING LABOR.

The advent of this phenomenon during the course of childbirth is regarded ordinarily with alarm by the patient and her attendants, as well as by the physician, until its cause has been determined. Although certain of these disturbances, such as albuminuric retinitis, are cleared up by an ophthalmoscopic examination, and some may be recognized by the history and the clinical picture, there are a number of other eye conditions which can be diagnosed only with difficulty.

Dr. S. Bauer (*Monatsschrift für Geburtshilfe und Gynäkologie,* June, 1906) reports a case of this kind, in which a parturient woman, otherwise apparently healthy, sudddenly became totally blind. The patient had for some years been subject to severe headaches which became worse towards the end of her pregnancy, and for three weeks previous to term were accompanied by considerable nausea. There were no convulsions. The blindness continued for five days, was then succeeded by hemianopsia, with complete recovery at the end of a month. Aside from a transitory edema of the retina and congestion of the veins, there was nothing abnormal to be seen on ophthalmoscopic examination. Albumin was abundant in the urine at the time of labor, but quickly disappeared. The puerperium was marked by high fever lasting nine days, and there were present abundant cerebral symptoms, including severe headaches, pain and spasm in the neck, delirium, and localized areas of tenderness. It was thought at one time that the symptoms might be due to an abscess in the occipital lobe and operation was even considered, but the subsequent favorable outcome showed the error of the diagnosis.

But seven cases of this kind have been reported, and in these the condition was referred to a uremic, *i.e.* an eclamptic, intoxication which involved the cortical portions of the optic tracts in one or both hemispheres and resulted in blindness. Bauer is inclined to regard this as a possible cause in his case, and looks upon it as an incomplete or aborted form of eclampsia, all the classical symptoms of the latter being present except the convulsions. It was Schmorl who pointed out that the convulsive seizure can be regarded only as a single phenomenon of the symptom complex which characterizes this peculiar toxemia of pregnancy, and its absence in certain exceptional cases may be explained by assuming that the intoxication is sometimes so severe that the stage of cortical irritation is entirely omitted and paralysis of the central nervous system appears at once. A similar difference in effect may be seen after the administration of large and small doses of any poison. If there is a form of eclampsia without convulsions, why, asks Bauer, may it not also be possible to have non-fatal cases, in which, to follow out Schmorl's reasoning, the degree of intoxication is not sufficiently severe to produce the necessary cortical irritation, temporary blindness being the only prominent symptom, and whatever organic changes occur being still reparable? There are many interesting features connected with this question, and it may be, as the clinical phases of the condition are more carefully studied, a new and more detailed classification of eclamptic cases will be formulated.

The Etiology of Syphilis Again.

The causative factor of syphilis has long formed a topic of entertaining, even if bitter discussion, though it was thought that the end had almost been reached with the discovery of the *Spirochæta pallida.* The evidence of the infectious character of the blood during the secondary stage of syphilis seems fairly well established and has been practically admitted by most syphilologists, but whatever the infectious principle may be, it is essential that it be recoverable from the blood during the secondary stage of the disease. W. E. de Korte of London claims, in the *Practitioner* for June, 1906, that *Spirochæta pallida* fails to satisfy this essential condition, and on no occasion in the blood of a large number of syphilitics which he examined did he once meet with this organism. He did, however, find another series of bodies which he believes are also protozoan in nature, but of their causal relationship to syphilis he seems to think it premature to speak. He observed a number of stages of this organism which he has grouped into a life cycle, and of these he has obtained photographs. The organisms are also flagellated, and on account of a euglenalike form which is present, de Korte ventures the suggestion that they belong to the class *Ciliata.* In addition to being found in the blood, these bodies were also isolated from the chancre and the condyloma, but with considerable difficulty.

Carcinoma in Early Life.

The clinical picture of a carcinoma is so commonly associated with advanced life that the question of years alone is often regarded as for or against the presence of such a growth in formulating an opinion in a suspected case. Instances of carcinoma in early life have, however, been reported, and it would appear that their number has increased during recent years. It is impossible to say whether this increase is actual or due to improved diagnostic methods; but the fact remains. The most recent report of this kind deals with a case of rectal carcinoma in a girl of sixteen reported by C. G. Grulee in *Surgery, Gynecology, and Obstetrics* for June, 1906. The patient was weak and anemic, there was constipation with intermittent bloody stools and much abdominal pain. Examination disclosed a mass in the left iliac region which might have been taken for impacted feces. Later on a local examination showed that this mass involved the wall of the rectum above the sphincter and a bit of the tissue which was examined showed that the tumor was an adenocarcinoma. There is no statement of the further course of the disease, but the report is certainly interesting in connection with the small number of similar cases which have been observed which show that carcinoma, although infrequent, is liable to occur at any age.

A Method of Fixing Blood Smears.

The usual method of fixing blood specimens intended for histological examination has been by means of heat; and although this serves very well in most instances, there are cases in which it is desirable to employ some other procedure. The gradually increasing employment of aceton in histological work led Jagic (*Medizinische Blätter,* No. 24, 1906) to experiment with it as a fixing agent for blood specimens. It was found, on comparing the staining qualities of smears thus fixed with those treated by other means, that Erlich's triacid stain,

for example, which, as is well known, affords the best means of bringing out the neutrophile granules, gave excellent results in specimens fixed for five minutes in pure aceton. The nuclei, as well as the granules, are also found to take on a much darker coloring, and the outline of the former appear sharper than after simple heat fixation.

News of the Week.

A Proposed National Public Health Society.—Announcement is made of a meeting to be held in the Hudson Theatre of this city on November 15 for the purpose of forming a national society for the preservation of public health. The movement is supported by a score of religious, medical, and scientific organizations, and has been endorsed by many persons of prominence. The object of the proposed society is stated to be to obtain and disseminate accurate information concerning practices and conditions of every kind that are dangerous to the public health and morals, to prevent quackery, criminal practices in the healing art, adulteration of drugs, and the sale of narcotics and alcohol under the guise of proprietary remedies.

Harvey Society Lectures.—The second annual course of lectures given by the Harvey Society of New York will be opened on October 20, 1906, by Prof. A. E. Wright of London. Ten lectures are to be given during the year, the lecturers and dates being as follows: Oct. 20, A. E. Wright; Nov. 3, C. A. Herter; Nov. 17, W. T. Porter; Dec. 1, J. G. Adami; Dec. 15, George Huntington; Jan. 12, F. G. Benedict; Jan. 26, E. B. Wilson; Feb. 9, S. J. Meltzer; Feb. 23, W. T. Councilman; Mar. 9, Friedrich Müller. The officers of the society for the coming year are Graham Lusk, *President;* Simon Flexner, *Vice-President;* F. S. Lee, *Treasurer;* George B. Wallace, *Secretary,* and C. A. Herter, S. J. Meltzer, and James Ewing, *Council.*

Dr. David C. English of New Brunswick has been appointed editor of the *Journal of the Medical Society of New Jersey,* to succeed Dr. R. C. Newton of Montclair. In his salutatory Dr. English says that "the *Journal* is not to be the exponent of the editor's dogmatic beliefs or judgments. The editorials . . . will never . . . touch upon controverted questions in a manner calculated to call forth merited condemnation."

Difficulty in Obtaining Meat Inspectors.—It appears that under the present requirements some difficulty may be experienced in obtaining the necessary complement of meat inspectors for the Department of Agriculture to carry out the provisions of the new meat inspection law. Out of about 3,600 candidates, only 8 per cent. of those taking the civil service examination passed in the Eastern States, and so far only about 288 of the 500 new inspectors required have qualified.

Report of the Coroner's Office for July.—The figures published by the Coroner's Office for last month show that of 524 deaths in the Borough of Manhattan, 298 were "natural or sudden," and 226 were caused by homicide, self-destruction, and casualties. Of the latter 24 were by drowning and 2 caused by caisson disease. One was caused by a kick from a mule. The surface railways killed 18, other vehicles 12, automobiles 3, while the real murders were 2 by shooting and 4 by cutting. The suicides number 26, and include the first death caused by leaping from the Williamsburg Bridge.

Suicide in Europe.—Statistics of suicide in Germany show that since 1873 the percentage of suicides has almost doubled, and it is stated that in France the number of suicides increases each year by 1 to 100,000. Drowning, shooting, poisoning, and hanging have been, in the order named, the favorite methods of self-destruction in Hamburg of late. In Italy, a couple of decades ago, hanging and shooting claimed most victims, and suicides by drowning and poison were becoming rarer. At present the tendency has changed, and poisoning is taking the place of shooting and hanging methods. Suicide by poison in Italy used to be confined almost entirely to females, men preferring firearms. Now poison is equally in favor with both sexes. The reason for this is supposed to be the greater facility with which corrosive sublimate and other forms of mercury may be procured on account of their increasing use for domestic purposes in the past decade.

Beer Drinking in This Country.—The internal revenue bureau has published figures which seem to show that beer drinking is on the increase in this country, for during the fiscal year that closed June 30, 1906, something like 160,000,000 gallons of beer more than during the previous year were consumed. The receipts from spirits amounted to $143,394,055, an increase of $7,435,542 over the last fiscal year. The increase in the receipts from tobacco was $2,763,086, the total being $48,422,997. The total revenues from fermented liquors, practically all beer, were $55,641,858. The receipts from beer were $54,651,636. As each barrel of beer pays a tax of $1, this shows that the consumption of beer in this country in the last fiscal year amounted to 54,651,636 barrels, each containing 31½ gallons. In the fiscal year 1905 the consumption was 49,459,530 barrels.

Cigarettes in the British Navy.—In spite of the activity of the anticigarette crusade in England at present, the British Admiralty has just made a move which undoubtedly will do much to popularize this form of smoking in the navy. The sailors have recently been showing increasing appreciation of the cigarette, and the Admiralty, recognizing this, has determined to issue fine cut tobacco suitable for cigarette rolling at the low price of a shilling a pound.

Chicago Medical College and Northwestern University Consolidated.—The last act merging the Chicago Medical College and the Northwestern University was performed July 24, when the President of the former institution gave a quit claim deed to the Northwestern University for all of its property. The intent of the conveyance is that there shall be a complete merger between the College and the University, free of all claims, limitations and obligations existing by virtue of any contracts heretofore entered into between the two institutions.

Metropolitan Hospital and Dispensary.—Through the purchase of an adjoining building, the trustees have been enabled to increase the facilities of this institution from sixteen to thirty-four beds, including a babies' ward of ten beds. The present medical board consists of the following members: Visiting Physicians and Surgeons, Doctors F. H. Albee and E. W. Lee, in surgery; B. S. Talmey and J. A. Schmitt, in gynecology; M. Jackson and O. P. Honegger, in internal medicine; H. B. Sheffield, in pediatrics; M. Talmey and A. Schapringer, in eye, ear, nose and throat. Adjunct Visiting Physicians and Surgeons, Doctors G. A. Friedman, M. Cisin, R. Lewy, I. Grush-

law, J. E. Murphy, R. P. Muellenbach, M. Caspe, A. F. Dempewolff. House Surgeon, J. Van W. Smith.

Bequest to Philadelphia Hospital.—By the will of the late Horace M. Potts of Philadelphia, the sum of $5,000 is bequeathed to the trustees of the University of Pennsylvania for the endowment of a free bed in the woman's ward of the University Hospital.

Ambulance Accident.—While answering a summons to attend a man who had fallen to the sidewalk from a second-story window, a Hudson Street Hospital ambulance, in charge of Dr. Bryant, broke its rear axle. The surgeon and driver were unhurt, and the injured man was taken to the hospital in a big touring automobile, whose owner had witnessed the accident and offered his services.

Chagres Fever at New Orleans.—The Louisiana State Board of Health has ordered the steamer Whitehall, which recently arrived at New Orleans from Colon, be held at the Mississippi River Quarantine Station indefinitely. She came into port with barely enough well men to run her, and of her crew of twenty-one men three have died and sixteen others are in the hospital.

Flies as Spreaders of Cholera.—The Bureau of Insular Affairs has received information to the effect that the difficulty experienced in controlling the present outbreak of cholera in the Philippines is to some extent due to the unusual prevalence this year of flies. Dr. Heiser of the Philippine Bureau of Health has ordered that every effort be made to destroy the pests, and that all places where food stuffs are stored be kept screened.

Death of Another Centenarian.—The oldest inhabitant of Bethel, N. Y., a woman reputed to be 109 years old, died on August 3. A year ago she became blind, but she was active until a week before her death. Her husband, well and strong at 92 years, survives her.

Health Statistics of Boston.—The total number of deaths reported to the Boston board of health for the week ending July 28 was 211, against 248 for the corresponding week last year, making the death rate for the week 18.27. Of this number 124 were males and 87 females.

Examination for Undertakers in New Jersey.—Under a law passed some months ago, Governor Stokes of New Jersey has appointed a State Board of Undertakers and Embalmers, before which all persons wishing to engage in these occupations must in future pass an examination. A feature of the law is that the use of embalming fluids containing arsenic is forbidden.

The American Association of Obstetricians and Gynecologists will hold its nineteenth annual meeting in Cincinnati, on Thursday, Friday and Saturday, September 20, 21, and 22, 1906. The Fellows of the association residing in Cincinnati constitute the committee of arrangements, of which Dr. Charles Lybrand Bonifield, 432 West Fourth Street, is the chairman, and Dr. Magnus A. Tate, Vindondissa Building, is the secretary, either of whom will furnish information to members and guests upon application . The President of the society is Dr. John Young Brown of St. Louis, and the Secretary is Dr. William Warren Potter of Buffalo.

Ohio Valley Medical Association.—The eighth annual meeting of this association will be held in Louisville, November 14 and 15, 1906. The chairman of the committee of arrangements is J. Garland Sherrill of Louisville.

Rhode Island Franco-American Medical Society.—At the meeting of this society, held at Pawtucket, R. I., on July 24, with the President, Dr. C. H. Boucher, in the chair, the charter of the association was accepted and a constitution and by-laws accepted. The next meeting will be held in September in Woonsocket.

Association of Colored Physicians.—A new medical society was formed in Boston on July 19 by the colored physicians of Massachusetts, and the following officers were elected: *President,* Dr. W. C. Lane of Cambridge; *Vice-President,* Dr. H. G. McKerro, of Worcester; *Secretary,* Dr. Thomas Patrick of Boston; *Treasurer,* Dr. J. B. Hall of Boston; *Executive Committee,* Dr. S. E. Courtney, Dr. I. L. Roberts, and Dr. H. C. Ross, all of Boston.

Obituary Notes.—Dr. William H. Taylor, medical inspector U.S.N., retired, died on July 30, at the naval station at Honolulu. He was made an assistant surgeon in 1859, and during the Civil War served on the *Savannah,* the *St. Mary's,* and the *Iroquois.* He received his appointment as medical inspector in 1876 and was placed on the retired list in 1881.

Dr. Charles F. Hermann of Brooklyn died at Waterbury, Conn., on August 2, at the age of thirty-six years. He was in Waterbury and received his medical degree from the Long Island Medical School. His death was due to infection following a wound of the foot received from a nail in his shoe.

Dr. Edward Hartshorn of Somerville, Mass., died at Berlin, Mass., on July 26, at the age of eighty-nine years. Dr. Hartshorn studied medicine at the Dartmouth Medical School and later received his degree from the Harvard Medical School in 1840. He practised for some years in Berlin, and in 1870 removed to Somerville.

Dr. Robert M. Whitefoot of Bozeman, Mont., died on July 25, at the age of sixty-six years. He was born in Philadelphia and was graduated from the Georgetown, D. C., Medical College in 1868. He went to Montana as army surgeon in the same year, and in 1881 he retired and located in Bozeman. He was made a member of the State Board of Examiners in 1890, and in 1896 he was appointed Surgeon-General of the National Guard of Montana. He was twice president of the Gallatin County Medical Society, and for some years was health officer of Bozeman.

Dr. Jerome B. Greene of Providence, R. I., died of apoplexy on July 27, at the age of seventy-five years. He was in the midst of an address before the members of the Fifth Rhode Island Artillery when his death occurred almost instantaneously. Dr. Greene was born in Uxbridge, Mass., and received his medical degree from Jefferson Medical College in Philadelphia. He served through the Civil War as assistant surgeon, and in 1865 he settled in Providence, where he practised until about twelve years ago.

Dr. John H. Love of Ventura, Cal., died of paralysis on July 23, at the age of fifty-nine years. He was a native of Ohio, but had practised in Ventura for many years and was county physician at the time of his death.

Dr. William F. Cornick of Princess Ann, Va., died on July 26, at the age of sixty-nine years. He was a native of Norfolk, Va., but had lived in Princess Ann for some years.

Dr. Stanton B. Drew of Jacksonville, Fla., died on July 30 after a short illness.

Dr. R. E. Brown of Milligan, Fla., died suddenly at Pensacola on July 27.

Correspondence.

FITTING GLASSES, ETC.

To the Editor of the Medical Record:

Sir:—Dr. George M. Gould of Philadelphia, in your issue of July 21, criticises an article by me recently published in the Medical Record, "fearing," as he says, "it may mislead the incautious." Perhaps I am wasting my time and your space in replying to this criticism, and I would be sure of the fact were I certain that all of your readers were familiar with Dr. Gould's writings. It is for the benefit of those who are not familiar with them that I beg space for reply, and not for those who know him; because by most oculists, both in this country and abroad, Dr. Gould's writing have ceased to be taken seriously.

The criticism of my article was not inspired through fear of the incautious being misled, but because Dr. Gould's pet hobby—eyestrain—had been hit a blow on the head. Dr. Gould himself is seriously affected with eyestrain paranoia, a large amount of mental astigmatism, if you please, which does not require the use of cyclopegics to detect.

(1) In the first place, Dr. Gould is the merest quibbler. He even quibbles on the title of my paper, saying: "The fitting of glasses is considered as a part of the opticians' art." This from the great purist, who in his "Biographic Clinics," page 356, speaks of "a scientific pair of glasses."

(2) My critic says the epitome of the history of the discovery of glasses is made up of many sins of omission and commission, and that it has been much better done than here. Why did he not mention a single instance of omission or commission, and not waste the time of the incautious with generalities, which serve no other purpose than to make copy? As to it having been better done elsewhere, that is a matter of opinion, which I leave for my readers to decide.

Criticisms 3, 4, and 5 I shall consider collectively. Dr. Gould says: "The ophthalmoscope is made much of as a method of diagnosing (*sic*) refractive errors, but it is of *no use* to those who value scientific precision in such work." Of the ophthalmometer, among other things, he says: "I, myself, find it of *no use whatever*" (italics mine). Of the retinoscope he says: "Retinoscopy is the most accurate and trustworthy objective method of diagnosing (*sic*) errors of refraction." We have here the admission of Dr. Gould that *he* finds the ophthalmoscope and the ophthalmometer of no use in scientific refractive work; and I shall show by another quotation that he rarely uses the one other remaining objective test—retinoscopy—whose superiority he so loudly proclaims. "Biographic Clinics," Vol. 2, page 367, has this to say: "Not the least of the oculists' expertness consists in deducing the truth from such answers, and by a sort of unexplainable intuition reaching the diagnosis through the jumble of inaccuracies. *Rarely the objective method may be needed to untangle the mysteries*" (italics mine). Now this is *scientific* refraction work, according to Dr. Gould. Two of the objective tests tabooed entirely and the remaining one "rarely needed to untangle the mysteries." The correct glasses to be prescribed are found "by a sort of unexplainable intuition reaching the diagnosis through the jumble of inaccuracies." Such are the written statements of this accurate and scientific refractionist.

The critic even presumes to know my motive for discouraging the method of retinoscopy, saying: "It is because it requires carefulness, time, and conscientiousness on the part of the oculist." This statement concerning my motive has as much foundation in fact as most of the statements made by my critic, and I let it pass for what it may be valued at without further comment.

(6) "The epitome of the history of the discovery of reflex ocular neuroses is all wrong . . . it is a sorry jumble of inaccuracies and misstatements. The quotations from Fisher, Sachs, Dana, and others are delightfully funny." Such are a few of the statements made in criticism 6. For the benefit of my readers I may say Dr. Gould himself has written voluminously on this subject, both in the abstract and the concrete, and I respectfully refer my readers to these writings, citing but one case from them, by way of illustration of the accuracy of Dr. Gould's method of procedure. In Vol. 1 of the "Biographic Clinics," the life tragedy of De Quincey is treated of. De Quincey, though he never suffered with headaches, nor had any trouble with his eyes, until sixty-five years of age, is guessed to have had myopic astigmatism, which caused him to become an opium fiend at the age of twenty. The only medical testimony to be had in this case (Dr. Begbie) shows no tendency to eyestrain whatever, but the biographic clinician says: "More even than the physicians that attended and wrote about him, I would trust his (De Quincey's) calm statements about these things." And some seventy years after the fact, with the statements of an opium fiend as to his own condition, a diagnosis of the trouble is made.

(7) Dr. Gould is very emphatic in his criticism of Dr. Howe's article, quoted by me, in which Dr. Howe shows that the great majority of American oculists do not agree with Dr. Gould in his absurd claims about eyestrain. Of this article of Dr. Howe's, Dr. Gould says: "If your contributor knew several things about it, even he would realize how much less valuable it is than that blank foolscap page." Of course all the oculists who oppose Dr. Gould's views are wrong and he is right. Such is the position assumed by Dr. Gould lately in his writings and before medical societies, he claiming that he is practising ophthalmology solely in the interest of the patient, thereby intimating that the rest of us are practising in our own interests.

(8) In regard to criticism number eight, I agree with Dr. Gould that cyclopegics are necessary in refraction work, as he practises it, that is, rarely using the objective tests; and I also agree with him that refraction work is "most inexact," where unexplainable intuition is relied upon to reach a diagnosis through a jumble of inaccuracies and subjective tests.

(9) As to opticians doing "as good work (*gratis*, too) as oculists do who do not use drops," I may say I know of many instances where the optician has done even better work than oculists who do use drops, reducing the strength of the glasses and giving comfort to the patient who had been made miserable by the drop-using oculist. Especially does this happen to that class of oculists who believe in using cyclopegics in presbyopic cases.

(10) It is very "exasperating," I know, and also an "inexcusable" blunder, not to have given credit for the discovery of eyestrain, "the greatest discovery in medicine except vaccination and the germ theory of disease" ("Biographic Clinics," Vol 2, page 350); but I beg pardon for the oversight this time and will give due and proper credit in my next.

A. Edward Davis, M.D.

OUR LONDON LETTER.

(From Our Special Correspondent.)

PROF. M'KENDRICK ON PROGRESS OF MEDICAL SCIENCE—PARLIAMENT, AMBULANCES, JUVENILE SMOKING, MEDICAL INSPECTION OF SCHOOL CHILDREN—HEALTH OFFICERS' JUBILEE—NOTIFICATION—HOSPITALS—ITEMS.

London, July 22, 1906.

Special interest attaches to the graduation address at Glasgow University this year. It was delivered on Tuesday by Professor McKendrick, who intimated that it was also his valedictory address before resigning the chair he has occupied for some thirty years. He took as a subject the progress of medical science during his professoriate, passing in review some of the most striking advances. Preventive medicine had enormously reduced the mortality from fevers and infectious diseases, aseptic surgery had saved thousands of lives annually and made operations successful which were at one time impossible. Gynecology had become a well-defined branch, and bacteriology had assumed importance in every department of scientific medicine. Marvelous as were the discoveries of these thirty or forty years, the professor thought we are still on the road to others, some of which may perhaps revolutionize the medical art. Ideas, he said, preceded discoveries, and the best work is done by the thinker, who meditates over familiar phenomena, invents a working hypothesis to explain them, then appeals to observation and experiment. His experiments are thus not haphazard; he knows what to try. Thus great principles are first established. Practical medicine, he continued, is not a science, but an art based on the sciences of physiology, pathology, and pharmacology. It seemed to him that these three are becoming more and more closely connected, are fertile in new ideas which must influence our conceptions of disease and its treatment. The interdependence of organs is recognized, and it is seen that an organ may have more than one function. Further, morbid changes have a beginning, and if we could detect them at the very commencement we might perhaps modify their progress, if not avert them. Prof. McKendrick then reviewed some of the protective arrangements possessed by the body for resisting attack, and went on to remark how one idea leads to another, *e.g.* leucocytes were observed in the blood by the early microscopists, but it is only in recent days their importance has been suspected. Their ameboid movement was first observed, then their tendency to aggregate in inflamed parts, then the phenomena of phagocytosis. So the life history of microorganisms was studied and soon it was found that they might not be injurious *per se*, but by producing a poison. The next step was that the toxin in some mysterious way produced an antitoxin, by cultivating which remedies have been found for diseases caused by microorganisms. Nor is this the end of the wonderful story. It is found that in serum there may be bodies derived from the tissues which have antibacterial powers—opsonins. A new field of serum therapeutics seems to be

opening. Another idea referred to by the professor related to the ravages of disease revealed in the post-mortem room. It seemed a wonder, sometimes, not that the patient died of the disease, but that he lived so long with it. But the changes had been going on for years. Yet much may be done. He confessed, as he grew older, the crude scepticism of early days gave place to the recognition of how much can be done. Study, he said, *e.g.* the problem of helping a weak heart with digitalis. It will test your physiological knowledge. Examine your cases with a physiological and pathological eye, not through the medium of a text-book and descriptions of typical cases. Then use your remedies with pharmacological knowledge, with a definite idea how they can do good, and you will find satisfaction in your work.

After much desultory talk about our street ambulance service, the House of Lords has considered the matter on account of a bill proposed by the County Council. Everyone acknowledges that London should have a good service, but it seems undesirable to duplicate what exists. It would be better to coordinate. It was stated on behalf of the government that a conference would be summoned of the three bodies concerned, viz., the Home Office, the Police, and the County Council. It was thought that a scheme could be formulated by such a committee dealing with the subject as a whole, and their Lordships agreed to wait for it until next year.

A committee of the Lords has also reported in favor of severe measures against juvenile smoking, and of two bills before the House prefers the more restrictive. It is proposed to penalize the seller of tobacco or cigarettes to boys and to fine the juveniles themselves, besides authorizing the police to confiscate the treasured weeds of the youths they catch indulging in the forbidden pleasure.

In the House of Commons the question of the medical inspection of school children has received further attention. An important point was whether such inspection should be compulsory, and local authorities required to carry it out. Whether also it should be enough to examine the children when they began their schooling, or whether it should be repeated, become in fact supervision by the medical men at the expense of the ratepayers. Many diverse opinions were emitted. One member said that at Dundee a voluntary inspection revealed that there were 1,500 scholars with heart disease and 7,000 with defective sight. Sir W. Collins said that when the County Council took over the School Board's work there were two medical officers and six oculists on the staff. At once twenty-three medical men and six nurses were added, and these will be shortly much increased. He thought an anthropometric survey might be postponed. Nearly all the speakers professed sympathy but there were grave doubts expressed about the alleged degeneration of the race and the necessity of providing every child with free meals, free medical attendance, spectacles, and so on.

A deputation got up by the British Medical Association on this subject waited on Mr. Birrell on Monday and urged that inspection should be made compulsory. Dr. Buick said voluntary examinations had proved that a great number of children were inefficient, and the medical profession was convinced that much disease could be prevented by inspection. Sir V. Horsley advocated the Education Board dealing with the matter, and said leaving it to the local authorities would not satisfy the profession. Sir W. Broadbent went so far as to say diseases would be recognized in childhood and treatment would influence their moral and physical efficiency in later life. The minister in reply said, however desirable inspection might be, their scheme would not effect their object, and then he raised the specter of the rates. Yesterday, however, his tone changed. He went to a drawing-room meeting on behalf of the League for Physical Education. By that time his fear of the ratepayers seemed to have vanished and he told this select audience that he used to regard the three R's as sufficient for compulsion, but had since learned much. Now he spoke for a full curriculum for all healthy children, medical supervision of the unhealthy, defective, or weak, and not only instruction but plenty of play for all to improve the breed of the race. So he anounced his intention of a medical examination on entrance and a health register to be kept in every school.

The Incorporated Society of Medical Officers of Health celebrated its jubilee by a visit to Bath. Sir Shirley Murphy presided over the public meeting on Saturday, and a paper was read by Mr. Loch, in which it was stated that the income of London Charities (excluding those of a spiritual kind) amounted to £6,519,529, while the Poor Law expenditure reached £2,250,406, excluding that of the Asylums Board. He emphasized the fact that with better health and lower mortality, there was more dependence on the Poor Law and increased expenditure of charities. Dr. Weatherley of Bath advocated compulsory notification of phthisis and declared voluntary notices useless. He pronounced it a "crying scandal" that only about twenty-three Boards of Guardians were doing anything to stamp out the disease, and there were six hundred and seventy-nine boards in the country.

Notificationists are active in all directions, and most of them in favor of compulsion. At the Sanitary Congress it was proposed to establish an imperial system by which information should be officially transmitted between the various parts of the empire. One paper went so far as to advocate an international system of notifying the chief infectious diseases, which would doubtless be useful from an epidemiological point of view. There is already a nucleus of such a system in the reporting of cholera and plague, but whether other nations would consent to extend it seems very doubtful, if not quite improbable. At the International Sanitary Congress of 1903 the delegates opposed any extension.

You will remember the case I reported to you last March, in which an action was brought against Dr. Currie (and his partner) for alleged negligence in attending a lady in her confinement. It was contended that he conveyed to her scarlet fever. The jury found a verdict for the doctor, adding a rider that he had taken all usual precautions. On Wednesday the case was brought before the Court of Appeals on the pretense of misdirection of the jury, and that evidence had not been called as to the usual precautions taken by medical men. Counsel having spoken on behalf of the plaintiffs, the court dismissed the appeal without hearing counsel for the doctors.

Princess Christian of Schleswig-Holstein on Saturday went to Beninden, Kent, and laid the foundation stone of the first sanatorium for workers suffering from tuberculosis. The Princess is president of the national association for promoting such sanatoria. This is the scheme which the workers are to make self-supporting and which the friendly societies and trade unions undertake to maintain when established. The present building is to have 200 beds and is estimated to cost £50,000, including the land, about 250 acres. So far the workers have collected £1,000. The affiliated societies will give £65 per bed per annum.

Princess Louise, Duchess of Argyll, accompanied by the Duke, presided at an afternoon meeting of friends of Charing Cross Hospital, at the Hotel Cecil, to hear Lord Kilmorey expound a scheme for organizing local interest in the hospital. He said in its busy district there were more than 5,500 front doors giving access to the occupiers, who were prepared to give to many objects hundreds of miles away, and only 165 subscribed to this charity in their very midst, chiefly because they were never asked. He proposed to divide the district into twelve divisions, each with a committee to obtain from local people a penny a day to establish a maintenance association. The Princess agreed to be patron of the association and Lord Kilmorey took the part of its first president.

Dr. Wm. Henry Perkin, the discoverer of the coal-tar colors, has received the honor of knighthood. He first obtained mauve from tar in 1856, and for eighteen years continued at work on the subject. A jubilee of the coal-tar color industry is to be held on the 26th, when Sir W. H. Perkin will be presented with addresses from British and foreign societies.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

DENGUE EPIDEMIC—BLOOD FINDINGS IN THE DISEASE—INFECTION WITH PARAGONIMUS WESTERMANII—SANITARY IMPROVEMENT AT BILIBID PRISON—CHOLERA—EVILS OF THE ANTI-CANTEEN LAW.

MANILA, P. I., June 16, 1906.

WITH the advent of the rainy season, which set in a few weeks ago, dengue made its appearance in Manila. The disease has been increasing by leaps and bounds and has now almost reached epidemic proportions. The present outbreak is characterized by profuse typical eruptions in almost every case. This latter is a noteworthy point, because it has frequently happened in the past that an outbreak occurred in which no eruption was observed.

In this connection it might also be of interest to recall the extensive laboratory work which has been done at Cavite during the past six months by Dr. E. R. Stitt of the United States Navy. He has been unable to verify the observation of Graham and others that a micrococcus was the cause of the disease, and, furthermore, he was unable to prove the mosquito transmission by the methods that have been published up to the present time. In the experience of Dr. Stitt, the most characteristic blood findings in dengue are the absence of protozoa, the leucopenia, the diminution of the polymorphonuclears, and the great increase in the small lymphocytes in the early part of the

disease, which is followed by a greater proportion of large lymphocytes in the final stages of the disease, and a great increase in the mononuclears during the convalescence.

At an autopsy which was recently held upon one of the prisoners at Bilibid Prison, the *Paragonimus westermanii* was found, not only in the lungs, but in all the abdominal organs, and in the brain a particularly large number were found.

The Bureau of Health has been in charge of the sanitation of Bilibid Prison for over six months now, and it will perhaps be of interest to observe the reduction which has taken place in the mortality at that institution. In August, 1905, the mortality was at the rate of 191.79 per thousand per annum, while the average mortality for December, January, February, and March was 58.99 per thousand per annum, from which it will be seen that a reduction of 132.80 per 1,000 has actually taken place. This latter mortality is, of course, much higher than it should be. The average death rate for the Philippines is almcst 20 per thousand less than this, and when it is considered that the outside death rate is effected by infant mortality and the aged, and that the inmates of Bilibid are mostly strong, robust men in the prime of life, it will be seen that a still further reduction in the death rate should be effected. The mortality, for instance, at the Ohio State Penitentiary is 15 per thousand. In a tropical climate, and more particularly in the present condition of the prison, it is probable that it will never be possible to reduce the rate as low as that of similar institutions in the United States. The great improvement in the mortality was brought about principally by a more rigid daily inspection of the prisoners, and an insistence upon more frequent hospitalization than has heretofore been the case. The great importance of isolating and treating incipient cases of tuberculosis, dysentery and similar diseases will be readily appreciated. It is quite probable that there is no instance of the value of preventive or prophylactic medicine being more conclusively proven than by the figures cited.

It is believed that important factors still influencing the mortality rate are overcrowding and the present insanitary method of collecting and disposing of excreta. The first factor can be removed only by providing more room and the second by the installation of a sanitary plumbing system.

Many of the deaths in Bilibid are due to pneumonia. It is believed that many cases can be indirectly traced to the present insanitary bamboo bunks. These latter are infested with bed-bugs, ants, rats, mice, and other vermin, and prisoners frequently, in preference to sleeping in these bamboo bunks, will climb down during the night and lie on the cement floor, thus contracting colds, breathing the foulest air, and otherwise lowering their resistance to any pneumonia organisms that may happen to be present. To remedy this, it is proposed to install sanitary bunks which will be constructed of iron pipe frames to which will be attached canvas hammocks, which can easily be taken down from time to time and disinfected and washed.

A case of cholera made its appearance during the week among the troops at Fort William McKinley. The disease was probably contracted at the town of Pasig, which is but a short distance away.

Owing to the anti-canteen law a great many low dives have sprung up at Pasig, and they are much frequented by the soldiers. The sanitary control of the town is not vested in the military authorities, but in the municipal officials, whose judgment about sanitary matters is no doubt often influenced by the sources from which much of the town revenue is derived. This is another illlustration of the undesirable conditions that may arise as a result of the anti-canteen law. The soldiers have been refused permission to visit Pasig, and no further cases have made their appearance among them.

Behavior of Foreign Bodies in the Nasal Cavity.—Santi Pusateri has studied critically and experimentally the behavior of foreign bodies when introduced into the nasal cavities. Such bodies may act simply by pressure on the surrounding tissues, producing atrophy of the nasal bones, necrosis of the cartilages with formation of new connective tissue, deviation of the septum and increase in the size of the cavity of the nose. Again it may set up an inflammatory reaction which results in encystment after some time, and the formation from the nasal secretions of a stratified calculus. After a few days of presence in the nose it may set up suppuration and then form a calculus. Or the stagnant purulent secretion may produce an infection of the cribriform portion of the ethmoid extending into the cranial cavity. The body may become incapsulated in the septum after producing necrosis of that organ.—*Archivio per le Scienze Mediche*, Vol. XXX.

Progress of Medical Science.

Boston Medical and Surgical Journal, August 2, 1906.

Gastromesenteric Ileus.—John M. T. Finney believes that acute dilatation of the stomach and gastromesenteric ileus can not be differentiated clinically; that obstruction to the lumen of the duodenum by the root of the mesentery and the contained superior mesenteric vessels, has been demonstrated, and is probably of more frequent occurrence than has been supposed; that whether this is primary or secondary to the gastric dilatation, or whether this relationship is a constant one, has not been determined; that the diagnosis would appear to be more easy than past failures seem to indicate; that the use of the stomach tube and avoidance of dorsal decubitus offer better results probably than secondary operation, owing to the unsatisfactory conditions existing; that with earlier diagnosis and the early institution of the measures suggested, a reduction of the present high mortality rate can be expected.

Spontaneous Rupture of the Heart in a Case of Senile Dementia.—Harry W. Miller reports the case of a man, 83 years old, who had a spontaneous rupture of the heart as a result of myomalacia cordis, the accident being determined by mental and physical excitement. The infarct, which had existed sufficiently long to show signs of repair, resulted from a thrombus in the anterior coronary artery. The most noteworthy feature of the case was its rarity. Krouskoff reports only three cases in 8,000 autopsies. The site of the rupture in relation to the area of degeneration at the apex of the left ventricle is somewhat unusual, yet it can be correctly designated as a rupture of the left ventricle near the tip, a common location. Odriozola reports rupture of the left ventricle in 96 out of 132 cases which he collected from the literature. The age of the patient, and the resulting condition of the arterial system, are predisposing conditions almost invariably cited in cases of spontaneous heart rupture. The preexisting disease, anemic necrosis, is regarded as a less frequent cause of heart rupture than other degenerative diseases of the myocardium.

New York Medical Journal, July 28, 1906.

The Ocular Factors in the Etiology of Spinal Curvatures.—H. Augustus Wilson discusses the relations that exist between certain forms of acquired spinal distortions and postures of the head. The more extensive the bony changes the less prospect is there for betterment, and remedial measures then employed are at best but palliative. He confines his discussion to the possible effects of acquired postures of the head in using the eyes, whether occurring alone or in conjunction with other recognized causes of scoliosis. He refers to several papers by Gould, from which are deduced certain facts and explanations. It can be demonstrated upon any normal person that a certain astigmatic (glass) lens, placed so that the artificial astigmatism produced shall be at axis 75°, will obscure vision unless the head is tilted 15° to the right, in order to bring vertical objects into clearer vision. If a patient has 75° astigmatism, because of curvature of the cornea, he will be compelled to tilt his head to the right to see clearly. These truths depend upon other factors, such as right-handedness and the presence of an equal or better acuteness of vision of the right eye. If the patient is left-handed he is also left-eyed, and the left eye then becomes the chief factor in the production of head tilting. In the dextral posture the body is curved to the left and the head and neck more curved, rotated to the right, and spirally upward, so that the cervical portion of the vertebral column has three abnormal positions, curves, or twists; viz., a curve with convixity to the right, a rotation on itself, and a spiral twist. These vicious positions are of purely ocular origin. The therapeutics of the functional stages of spinal curvature should be to remedy any existing head tilting and to stop the morbid writing posture by placing the paper opposite the right shoulder, when sitting squarely and upright before the desk, and to incline the desk leaf at an angle of at least 30°. Again the orthopedic surgeon should direct the use of such remedial measures as have been determined as best adapted to securing full, normal function and reestablishing verticality.

Should Cold Baths be Given for Fever in Young Children?—Charles O'Donovan calls attention to some of the drawbacks of cold bathing in children, yet in spite of them he advises the use of cold baths in children, even infants, whenever the high fever and flagging powers point to the possibility of an impending collapse; and the child is to be tubbed, not only once, but whenever the same symptoms return in sufficient severity to call for such treatment. He considers this the only available means to check the rapidly rising temperature of malignant scarlet fever. The proper treatment of convulsions of young children should be the

cold, rather than the hot bath, to reduce the fever and calm the over-excited nervous system of the child. Terror and fright are not bars to its usefulness.

Remarks on Albuminuria, Cylindruria, and Bright's Disease.—S. J. Meltzer says the urine of all normal persons contains minute quantities of albumin. This is physiological albuminuria. A number of individuals have traces of albumin in the urine passed after a night's rest, and more show albumin after muscular effort, but this is still physiological. About one-fifth of all persons have during adolescence some degree of albuminuria; some of these and some other individuals show an orthostatic form of albuminuria; these forms are not physiological. Again, there are cases of simple albuminuria which do not belong to any of the types described. They last for many years without showing any cyclic or postural character. The patients never had or have other symptoms indicating a disease of the kidney, or in fact any other disease. Albuminuria in anemia or in fever, which disappears with the defervescence, may be quoted as an instance of pathological albuminuria which is not of nephropathic origin. However, this is not beyond dispute. The history of the diagnostic value of casts is in some respects a repetition of that of albuminuria. Cylindruria is nearly a normal phenomenon occurring very frequently in normal individuals, and is easily brought about by the same factors which produce albuminuria. Albuminuria and cylindruria resulting from stimulation of the normal kidney are only temporary, but those due to actual disease of the kidney are more or less permanent. Another important difference is that the latter forms of albuminuria and cylindruria are a good deal more extensive than the former. The continuous presence of albumin and casts of different varieties after the patient is put to rest and withdrawn from injurious influences speaks for Bright's disease, but those are not pathognomic symptoms, and only form one link in the chain of signs and symptoms which point to a diagnosis of Bright's disease.

Journal of the American Medical Association, August 4, 1906.

The Hospital Problem.—Bayard Holmes points out what he considers some defects in the hospitals of this country and their management. Having been founded largely from charitable motives, to relieve suffering rather than to restore to health and usefulness, they lack those postoperative gymnastics and hydriatic methods that form so large a part of the treatment in the hospitals of Europe. Our hospital trustees are supreme and the medical staff are their underlings, and it is often impossible for the hospital staff to secure what in their best judgment is essential for the good working of the institution. The use of hospital positions unduly for personal benefit is also criticised, the lack of other remuneration, the hampering of clinical work and of the utilization of the hospitals for instruction, the use of the hospital for the personal aggrandizement of some one overshadowing member of the staff, are all included in the indictment. The hospitals should be a part of the armamentarium of the profession, and it should control them.

The Mouth and Systemic Diseases.—J. E. Power calls attention to the mouth as a favorable place for the incubation of bacteria, the saliva having little or no antiseptic properties, and shows how it is in fact a perfect hotbed of microbes, many of them pathogenic. The conditions of their transmittal to other parts of the organism and the very numerous methods by which infection can be introduced into the mouth from outside, are duly noticed, and cases showing the effect of mouth conditions in producing general disorders are reported. Glandular swellings, cardiac involvement and tuberculosis are specially mentioned as having been directly traced to mouth infection, and the practice of such eminent authorities as J. H. Musser of including mouth sterilization as one of the progressive steps in the treatment of pneumonia is mentioned with approval. Other disorders, such as pulmonary gangrene, and liver disease, connected with oral uncleanliness, are also mentioned, and the importance of the condition of the mouths of both patient and operator in surgical cases is also noted.

The Treatment of Bone Cavities.—J. E. Moore gives his experience with the Moorhof "bone wax," composed of 20 parts iodoform, 40 parts spermaceti, and 40 parts of oil of sesame, which is warmed to 50° C. and poured into the cavity previously prepared, where it immediately solidifies. The cavity must be thoroughly cleansed and washed with 95 per cent. carbolic acid, then in about two minutes the acid should be washed out with alcohol, and must be thoroughly dried before pouring in the wax, which will not fill all the cavities if moisture exists. Moorhof uses a hot blast for this purpose, but it is not essential. Of course, the bloodless method must be employed. When the wax is hardened the periosteum and other tissues are closed with catgut sutures and a dry gauze dressing is applied and held in place by a roller bandage before the rubber bandage is removed. In case there is good periosteal covering no drainage is necessary, and usually primary union is secured. When soft parts come in contact with the wax, temporary drainage is advisable. In case immediate closure is impossible, he still finds this method applicable, and states that it can also be used in case of chronic bone abscess after thorough cleansing and sterilizing. A disadvantage of the method is the expensiveness of the material. The iodoform is the objectionable element, and Moore has experimented with success with the use of iodine flakes in its stead. He gives the following formula: Spermaceti, 8 parts; olive oil, 2 parts; iodine, 1 per cent., the iodine being added after the other material, as heating volatizes it.

The Medical Treatment of Gallstone Disease.—R. W. Wilcox, New York, maintains that gallstone disease is primarily a hepatic disorder, and the congestions and inflammations of the portal system, the infectious catarrhal conditions of the bile ducts, and the faulty formation of bile in the liver, are the things that need to be attended to, and these are purely medical matters. The advantage of spa treatment is in the medical control in such places of the habits and diet, but practically as good results can be obtained at home. The diet should be a mixed one, the meals limited in amount, but at frequent intervals, to insure a constant flow of bile, with plenty of plain or feebly mineralized water at each. Alcohol should be prohibited. Exercise, especially out of doors, is important. He prefers salicylic acid to the salicylates, because it is both a biliary and an intestinal antiseptic, which the salicylates are not. Of the bile acid salts, sodium glycocholate in from ½ to 3-grain doses, as frequently as necessary, is the best. He also speaks well of phenolphthalein as an intestinal antiseptic; acid sodium oleate, salicylic acid, each 1½ grain, phenolphthalein, 1 grain, menthol, ¼ grain, in a pill; this allays nausea, acts as an intestinal antiseptic and promotes peristalsis. From four to eight of these pills in a glass of hot water once or twice daily have proved very efficient in gallstone disease. The elimination of the gallstones of the hepatic variety (bilirubincalcium) is generally rapid. Painless elimination is best achieved by administering amyl valerianate (15 minims in capsule) two hours before breakfast and after supper.

The Lancet, July 21, 1906.

The Influence of an Excessive Meat Diet on Growth and Nutrition.—D. Chalmers Watson in 1905 drew attention to the remarkable increase that had taken place in the consumption of animal food in England during the past fifty years (see MEDICAL RECORD, July 22, 1905, page 152, for abstract). During the past year he has made observations on the influence of a meat diet on the growth and general nutrition, and the paper deals with the clinical results obtained by feeding rats on an exclusive flesh diet. A summary of his results shows that growth is retarded, sterility is induced if the diet is commenced in very early life, the power of lactation is diminished, a permanent weakening of the resisting power of the animal is induced by the use of an excessive meat diet in early life, the animals succumbing to disease at an unusually early age, and there is a high death rate in the offspring of animals fed on an excessive meat diet. The facts recorded have an interesting bearing on the two questions of physical deterioration and high infant mortality, and there is no doubt but that several factors are concerned in their production, the foremost place being given to the question of diet. The defects in diet may lie in one of several directions, and more light should be thrown upon this by experimental medicine. The main interest in his experimental results lies in the clear evidence submitted that an excessive meat diet can itself induce in animals defective general physique, deficient powers of lactation, diminished fertility, and high infantile mortality. He believes that these symptoms are, to an important extent, comparable to those prevailing in the human subject at the present time.

Outbreak of Pneumonia in a Reformatory School.—Thomas Oliver reports an outbreak of pneumonia occurring in an industrial school, in the neighborhood of Newcastle-upon-Tyne, which has an accommodation for 200 boys, and is nearly always full. In all, eight cases of pneumonia occurred in eighteen days, and the ninth and last case, the only fatal one, occurred fifteen days

later. In only one case was the tubercle bacillus found. The youths were all quite well four years after the outbreak. The illnesses were ordinary croupous pneumonia and there was nothing unusual or peculiar in the course they ran. Most of the cases occurred in one large dormitory, in which the sleeping accommodations were overcrowded and ventilation defective. There was nothing to suggest an influenzal origin.

Cessation of the Pulse During the Onset of Epileptic Fits.—A. E. Russell says that, although it is true that such cardiac arrest is not a common or constant phenomenon in epilepsy, it merits greater consideration than it has received. Cardiac arrest may precede the development of the fit, and it is well known that stoppage of the heart for a sufficient length of time will give rise to attacks of unconsciousness and convulsions, the so-called Stokes-Adams syndrome. If observations were made on the pulse at the onset of fits in more cases, he believes it would soon become established, whether such cardiac arrest was of occasional or frequent occurrence.

A Case of Schönlein's Purpura.—Edward C. B. Ibotson reports an interesting case, which illustrates the following points: The combination of wheals and purpura, a combination which is diagnostic if not pathognomonic; a moderate pyrexia at the commencement of the illness; swelling of the knee and prepuce, and rapid beneficial action of suprarenalin.

The British Medical Journal, July 21, 1906.

A Note on the Effect of Bodily Exertion on the Opsonic Index of Healthy Persons.—G. G. Ellett examined the blood of several men training for a boat race, which gave evidence that severe exercise has some influence in lowering the opsonic index, even in healthy persons, in whom there can be no question of autointoxication, as is claimed in the case of the tuberculous patients.

Large Calculus of Ureter Removed by Suprapubic Cystotomy.—Rushton Parker reports the case of a man, aged 49, who complained of pain in, and prolapse of, the rectum with a tumor. The duration of the symptoms had been about six months. Examination revealed a tumor about the size of a walnut, felt with the finger in the rectum. A radiograph of the pelvis showed a distinct shadow of an oval shape suggestive of a calculus. The bladder was sounded, but nothing found, while the finger in the rectum passed between the sound and the tumor. No urinary symptoms had ever been noted. At operation a stone was removed from the right ureter, close to the bladder. It weighed a little over three-quarters of an ounce. Its exterior was blackish in color, presumably due to oxalate of lime, and the surface was sharply serrated. The interior was in irregular layers, or urate of ammonia and oxalate of lime apparently. No urine at all came from the right ureter, while the discharge from the left was normal. It seems likely that the function of the right kidney was seriously impaired. One could not help suspecting stone in the right kidney, but opportunity of submitting the patient to *x*-ray photography was not given.

A Case of Actinomycosis of the Abdominal Wall.—Archibald Cuff reports this interesting case, which was produced by an infected foreign body, which had escaped from the intestine. For at least eighteen months previous to the discovery of the abdominal condition, the man had a decayed molar tooth, which he was accustomed to pick with a piece of straw. He was hardly ever without a piece of straw in his mouth. Three months before he noticed the lump the tooth broke off, and he did not put a piece of straw in his mouth again. The course of events in this case was probably this: A piece of infected straw, bearing spores of the ray fungus, was swallowed by the patient, and a small particle penetrated the colon and entered the abdominal wall, setting up the disease there.

The Value of Calcium Iodide in the Treatment of Ulcers.—G. Arbour Stephens says that the effect derived from the use of this agent was more than could be expected, for its effect in reducing thick, callous edges into thin, healing ones, was little less than miraculous. He reports cases and emphasizes the important part played by calcium in health and disease.

Berliner klinische Wochenschrift, July 16, 1906.

Modern Renal Surgery.—Kümmell contributes a very extensive paper on this subject which is not adapted for reproduction in brief. He reviews the various methods of functional diagnosis and also discusses the results he has obtained in the operative treatment of the various kidney diseases, but most of the paper is devoted to a discussion of the reliability of cryoscopy of the blood as an index of renal efficiency. This method has been attacked by many other authors, but Kümmell continues to regard it as exceedingly valuable, and states that in over a thousand cases he has never found that it led to misleading conclusions. He considers that a drop in the freezing point of the blood indicates that the two kidneys together are not perfectly efficient, and that if the freezing point falls to —0.6, experience has shown that nephrectomy should not be performed A nephrotomy may be done, to be followed later on by nephrectomy if the freezing point improves, and has risen to the normal, but if this does not occur the kidney should not be extirpated. No one method alone should be relied on in renal diagnosis, but as many as possible should be applied, catheterization of the ureters and investigation of the separate urines being especially important. If all the diagnostic means now at our command are utilized Kümmell believes that the diagnosis of affections of the kidney can be made with what closely approaches certainty.

The Early Diagnosis of Tuberculosis.—Blume says that of late it has become the custom to attach less importance to the bacteriological examination of the sputum as a means of early diagnosis of tuberculosis, on the ground that the condition should be recognized, if possible, before the sputum becomes abundant. The author describes a procedure by which he has been enabled to demonstrate tubercle bacilli in a considerable number of cases in which there was neither cough nor expectoration. His method consists in collecting some of the laryngeal mucous on a pledget of cotton on a laryngeal probe and making a smear with this on a slide, which is then stained in the usual way. The histories of nine cases in which this procedure was successfully used are given.

Münchener medizinische Wochenschrift, July 17, 1906

The Part Played by Mine Infections in Epidemics of Cerebrospinal Meningitis.—Jehle, after having investigated the conditions attending epidemics of this disease in several Silesian mining towns, comes to the conclusion that the rôle played by the mines in the transmission of the disease is a very important one. He considers that epidemics of meningitis are the result of the infection of one miner by another while at work in the mines themselves, and that this transmission of the causative organism takes place through the sputum, and the use in common of tools, drinking vessels, etc. The women and children are then infected by these workmen in their homes, young children being especially exposed to direct infection. Miners coming from an infected district are to be looked upon as possible bacilli carriers, and to be treated accordingly. In order to prevent the spread of epidemics, the author believes that it is of the greatest importance to keep miners, whose children are sick with the disease, out of the mines for such a period until it is certain that they can no longer act as bacilli carriers, though there is no objection to their working above ground.

Attempts at Suicide.—Rothfuchs presents a review of 375 cases of attempted suicide observed during the last five years in the Harbor Hospital at Hamburg. During 1903 the official reports showed that in Prussia 7,470 deaths were due to suicide, representing 21 to 100,000, whereas in 1873 the figure was only 11 to 100,000. It is stated that in France the number of suicides increases each year by 1 to 100,000. Of the author's cases, 48 were insane, 13 were suffering from delirium tremens, and 16 others were mentally incapacitated through some form of pathological intoxication; that is, 76 individuals, or 20.26 per cent., were not responsible for what they were doing. Alcohol appeared to be responsible for the largest proportion of these attempts at self-destruction, and the author considers this as one of the most important causes for the modern tendency toward increased prevalence of suicide. Of the 375 cases, 53, or 14.13 per cent., ended fatally. Drowning, shooting, poisoning, and hanging were the favorite methods chosen in the order named, and by far the greater proportion of deaths were the result of the use of firearms. Of the poisons, hydrochloric acid and lysol were the most frequently used agents. In conclusion, the author inveighs against the custom still prevalent in some regions of refusing the ordinary form of burial to suicides, basing his objection mainly on the ground that so large a proportion of suicides through mental disease or for other reasons are not responsible for their actions.

Sepsis in Adults Due to the Bacillus Pyocyaneus.—Rolly reviews the literature bearing on the subject of the pathogenicity of this organism, and describes a case coming under his observation, which, he believes, demonstrates the fact that the bacillus pyocyaneus by

itself is capable of playing the rôle of an invading pathogenic organism in adults, as well as in children. His patient was a woman of twenty-eight years, who apparently was infected through the pregnant uterus, and who died on the eleventh day. The bacillus pyocyaneus was identified during life, both in the blood and in the cerebrospinal fluid. The autopsy revealed, among other conditions, a vegetative endocarditis with metastatic abscesses in the kidney, spleen, intestine, and aorta. In addition, there was a purulent cerebrospinal leptomeningitis and a lobular pneumonia. In regard to the clinical course of pyocyaneus sepsis, the author states that many different types may be encountered; in the present case the meningeal symptoms were the most prominent.

Deutsche medizinische Wochenschrift, July 19, 1906.

Nucleated Red Blood Cells.—Engel discusses the origin and significance of nucleated red blood cells, as well as the mooted point concerning the disappearance of the nucleus of the normal erythrocyte. He agrees with those who consider that the basophilic granulations of the red cell in many instances are the result of disintegration of their original nuclei. It is possible that two varieties of basophilic granulatons exist, of which the one is the result of karyorrhexis and the other is due to degeneration of the protoplasm. The author regards erythrocytes with basophilic granulations as being immature blood cells, which, when they occur in anemia, malaria, lead poisoning, etc., are extruded from the bone marrow into the blood as the result of the toxic action underlying these conditions, just as for example unripe polynuclear leucocytes appear as myelocytes.

Menstrual Fever and Menstrual Sepsis.—Riebold bases his conclusions on a study of 2,000 patients observed during the past two years. As a result of these he concludes that in many cases elevations of temperature occur during menstruation which can not be explained in any of the ordinary ways. This menstrual fever occurs most often on the third or fourth day of the period, though it may be earlier, or may even occur after cessation of the flow. This fever, as well as the leucocytosis of menstruation, the author believes, is due to the absorption by the uterus of toxic or infectious materials. During menstruation the uterus and its contents form a particularly good culture medium for bacteria, and the normal protective power of the vaginal secretion is abolished. The possibility of menstrual infections must, therefore, be taken into account in cases of cryptogenetic sepsis, and the author believes that the process of menstruation is of great significance in the pathogenesis of many febrile disorders. Not only is the not very rare menstrual fever caused by the absorption of bacterial toxins or other decomposition products, but through a similar toxin action numerous affections of the skin and nerves, which are observed during menstruation, such as erythemas, urticaria, herpes zoster, and neuralgias, may be induced. Of particular importance in this connection is the probability that numerous rheumatic affections, especially true cases of polyarthritis and of rheumatic heart disease, may originate in infection or intoxication from the menstruating genital tract.

The American Journal of the Medical Sciences, May 1906.

The Clinical Significance of the Urinary Nitrogen.—James Ewing and C. G. L. Wolf refer to the work of Folin. He made a most complete study of thirty normal urines, whose daily nitrogen content ranged from 2.7 to 16 grammes. If one finds in examination of a urine ratios outside these limits, it may be concluded that the metabolism is not normal. A pronounced metabolic disturbance may be expressed by slight subjective symptoms only, when the process may, at the same time, be giving an expression of disorder most forcibly through the urine. It is true in very many instances that there is a quantitative relationship between the variation from the standard and the degree of metabolic disturbance. There are, however, numerous exceptions to this. The possible influence upon the type of metabolism of certain physiological conditions, such as pregnancy, lactation, infancy, old age, and insufficient amounts of food to cover the heat exchange, is an important question. The estimation of single components of the urine is of little clinical value. The picture of the total nitrogenous excretion and its partition offers far more reliable clinical information. The writers declare that they are by no means certain how far the present knowledge of this complex subject will render this type of urinary analysis practically available to the clinician.

The Diagnostic Significance of Persistent High Arterial Pressure.—Theodore C. Janeway believes that with a 12 cm. armlet there can be little question that under conditions of physical and mental rest the upper limit of normal systolic pressure—the pressure necessary to obliterate the pulse wave in the bracial artery—may be taken as 145 mm., the lower limit 100 mm. He thinks it wise, when dealing with new patients, to consider no pressure below 160 mm. pathological. Marked and lasting elevation of the general level of blood pressure in any individual is a clear-cut and important disturbance of his normal circulatory physiology. After discussing a large series of cases in which there was persistent high arterial pressure, the writer declares the important point to be the physiological picture of chronic arterial hypertension as a type of cardiovascular disease, usually secondary to chronic Bright's, but at times unassociated with it. Many of the dangers to which the patient is subject, whether he be a nephritic or not, arise from this hypertension. The accurate measurement of blood pressure by the sphygmomanometer must prove a valuable addition to the methods of physical examination.

A Preliminary Study of Visceral Arteriosclerosis.—Harlow Brooks declares that the presence of diminished visceral function, with occasional and otherwise unaccountable elevations of the blood pressure, should, particularly in connection with possible etiological factors, lead to a suspicion of some localized, if not general, area of arterial disease. When, too, there is pain of the peculiar anginal character, location in some special organ may be within the range of possibility. At present diagnosis by the usual methods becomes possible only when the time of prevention or successful treatment is usually passed. The writer presents a series comprising 400 consecutive cases of arterial disease as they have appeared in his personal necropsical service. Disease of the coronary arteries predominates. Next in frequency are the arteries of the brain. The renal vessels appear third in rate of occurrence. Then follow the vessels of the pancreas, the liver, the splenic arteries and the vessels of the lungs. The first effect of the arterial disease appears in the parenchymatous tissues supplied by the vessels.

The Anatomy of the Parathyroid Glands.—John Rogers and Jeremiah S. Ferguson have found that the most convenient method for finding the parathyroid gland is to begin the dissection at the back of the pharynx. To do this, the larynx, trachea and esophagus, with the attached great vessels of the neck, and the thyroid and parathyroid glands are removed in one piece. The parathyroid glands generally lie behind and to the inner side of the lateral thyroid lobes. They are small, and they rapidly decompose, or rather undergo apparent autolysis. These bodies are flattened bean-or-kidney-shaped, generally surrounded with fat, and vary from a microscopic size to a diameter of one-quarter to three-eighths of an inch, rarely larger. Their color is a red or yellowish brown. The writers have found parathyroid glands in subjects of all ages. In infants they were a trifle larger in proportion to the size of the subject, and were thus more easily located than in adults.

Observations Upon the Form of the Red Blood Corpuscle of Man.—Henry E. Radasch concludes that: The majority, if not all, of the circulating cells are bell-shaped, and not biconcave. Their presence in the adult body, as well as that of the fetus, is shown by a study of the placenta. Their presence in the fetus and infant seems undoubted, as shown by their abundance and uniformity in shape and size, in the fixed tissues. Upon contact with the air the bell-shape is changed to the biconcave, the result of collapse. This is shown by the fixation of blood that has not been exposed to the air, on the one hand, and blood that has been exposed, on the other.

Vaccination Against Tuberculosis Through the Digestive Tract.—M. E. Roux and Vallée, in order to confer immunity upon calves, fed them with tubercle bacilli which had been killed. In November, 1905, the calves were made to swallow small quantities of living tubercle bacilli in order that they might become infected. Sometime later these animals reacted to tuberculin. Still later they failed to react. These investigators then injected virulent bacilli into the veins of these animals. They proved resistant, while the control animals died of generalized tuberculosis within a few weeks. This experiment shows that the calves were made immune against tuberculosis through the digestive tract following the first ingestion of bacilli. These experiments are not yet completed. —*Le Bulletin Médical.*

(Special Report to the MEDICAL RECORD)

(*Concluded from page 198*)

SECTION ON DISEASES OF CHILDREN.

Fourth Day—Friday, June 8.

Superstition in Teratology with Special Reference to the Theory of Impressionism.—Dr. EDWIN TAYLOR SHELLY of Atchison, Kansas, in this paper noted and defined the various theories entertained from time to time by the ancients in regard to the origin of fetal defects and deformities. He maintained that the maternal impression theory was both logically and biologically untenable. An appeal was made to the profession to try to uproot this popular superstition, not only because modern science demands it, but especially because innocent, sensitive mothers should be spared the awful crushing responsibilities which belief in this cruel notion so wrongfully inflicts upon them.

Constitutional Low Arterial Tension in Children.—Dr. LOUIS FAUGÈRES, Bishop of New York City described this condition as one probably having its origin in the nervous system, though the symptoms are circulatory. Young people with this defect presented habitually a very low arterial tension, so that the pulse, if found in other individuals, would suggest the prostration of acute or chronic disease. The condition was described as an habitual one. There was no heart lesion, no cardiac symptoms such as shortness of breath, or dropsy, and the kidneys presented no abnormality of function. The defect seemed to be in the peripheral circulation, due to a vasomotor relaxation which failed to produce the back pressure on the arterial system that was necessary for a normal tension and a proper cardiac stimulation. To differentiate such a case from a case of cardiac weakness it was pointed out that it was only necessary to make a demand upon the circulation by active exercise, or to observe the response in the case of acute disease. Such children were better as the result of mental and physical activity. The object of recognizing the condition was to place it in the category of constitutional conditions and not treat it as an accompaniment of a supposed anemia, cardiac disease, or as the constitutional effect of some local disease. The error likewise must not be made of confusing the condition with primary, or with secondary low arterial tension; the former having for its basis a true failure of the integrity of the circulatory apparatus; the latter representing an exhaustion due to the exorbitant demands of prolonged high arterial tension.

Dr. ARTHUR W. FAIRBANKS of Boston cited a case which had puzzled him, and suggested that the reader of the paper could throw some light upon it. The child had entered the hospital with enteritis. This had improved, but the child gradually became cyanotic, the whole body becoming more or less blue. The pulse was 80 and remained the same until death. No post mortem had been secured.

Value of Small Amounts of Human Milk in the Treatment of Infantile Atrophy and the Infections of Infants.—Dr. F. P. DENNY of Brookline read this paper, emphasizing the value of human milk in cases of infantile atrophy or any infection where the life of the infant was threatened. He assumed as a working basis that the human milk was of value in these conditions through the action of ferments. His experience had been chiefly at the Infant Asylum in Boston. The sick babies seldom had more than three nursings a day and four bottles. Only the sickest babies were nursed, and usually improvement began within a few days. This was attributed to the few ounces of breast milk received during the day. Cases were cited in which everything was done in artificial feeding to nourish the child, but in which the only hope lay in securing breast milk. In one case a wet nurse could not be obtained, and an effort to have a woman nursing her own child draw off some milk was successful. About three ounces of breast milk were given on the first day, resulting in a marked improvement. The practice of wet-nursing as now carried out should be revised. It was poor practice and not right to have a woman abandon her own baby for the nusing of the sick baby.

The Wet-Nursing of Foundlings a Pernicious Practice.—Dr. WILLIAM T. WATSON of Baltimore severely criticised this practice, and cited an instance occurring in Baltimore in which the nurse acquired syphilis.

Dr. H. MCCLANAHAN of Omaha cited a case in which a small amount of breast milk secured for an artificially fed baby enabled the infant to pass the critical point in its illness. Relative to the second paper, while he did not think foundlings should be deprived of any measure conducive to their well-being, he thought a satisfactory plan was not to allow them to be nursed until after three months of age, by which time if syphilis were present it would be manifest.

Dr. I. A. ABT of Chicago agreed that breast milk would tide over a great many sick children.

Dr. THOMAS MORGAN ROTCH of Boston endorsed Dr. Denny's estimate of the value of human milk in the feeding of infants with atrophy and other infections.

Dr. WATSON, in closing the discussion of his paper, emphasized the fact that he was speaking only of the practice of wet-nursing foundlings. In the case reported the baby was the child of a prostitute. He emphasized the fact that the syphilization of innocent women was inherent in the system and could not be prevented by the most rigid inspection; also that infection could be communicated by the most minute lesions in the baby's mouth and of the mother's breast.

Some Unheeded Principles Involved in the Dietetic Management of Infants in Hot Weather.—Dr. GODFREY R. PISEK of New York City presented the following conclusions: (1) In warm weather keep a light woolen garment over the abdomen to prevent sudden chilling of the skin and consequent heat retention by suppression of perspiration. (2) Bathe infants twice daily. (3) Give plenty of cool boiled water to drink, to replace that lost by evaporation. (4) Pasteurize the food to retard its decomposition. (5) If the weather is close or muggy, or the humidity is high, dilute the food with one-half boiled water. In very humid weather, with high temperature, stop milk altogether, and feed gruels until the humid condition is past. (6) On warm, humid nights do not give milk feedings, because the humidity is higher at night than in the daytime. (7) For diarrhea give calomel or castor oil to eliminate decomposing food. Stop all milk feedings temporarily. If the air is hot, but dry, milk feedings may be resumed quite rapidly. If the relative humidity is high, feed gruels to reduce heat production and also to starve out putrefactive bacteria and cautiously get back to the milk feedings. (8) Provide a circulation of air, as stagnant air soon becomes saturated with water vapor and no more perspiration can evaporate and absorb heat.

Dr. R. W. HASTINGS of Brookline spoke of the installation in one of the local hospitals of a plant the object of which was to freeze out the moisture of the air and make possible the bringing into the wards of air at a temperature of 70° with a humidity of 50; in other words, bringing to a baby in July and August a temperature and humidity like that of October.

Dr. SAMUEL AMBERG of Baltimore detailed a number of observations, the results of which seemed to be in accordance with Moro's observations, according to which the bactericidal power of the serum of breast-fed infants markedly exceeded that of artificially fed ones. But the variations observed within the single groups did not permit us to ascribe the higher value purely to the peculiar kind of

food given. It seemed that the state of the nutrition and the constitution might play a rôle in regard to the opsonic contents of the blood of infants.

Cerebral Palsies.—Dr. William J. Butler of Chicago, in presenting this paper, stated that the etiology of cerebral palsies in individual cases was not always easy to determine, because of late observation of the cases, or because autopsy findings obtained long after onset of the disease may, instead of the initial lesion, show secondary pathological changes. Prenatal palsies, it was stated, were due either to development defect or to vascular lesion. Birth palsies were due to trauma of the child's head, whether from prolonged pressure or unskilled forceps delivery. Asphyxia might be an active factor. Postnatal palsies were said to result from (1) trauma, resulting in hemorrhage and sometimes brain contusion; (2) vascular lesions, hemorrhage, embolism, or thrombosis; (3) inflammatory changes; (4) rarely a tumor. The pathological changes of infantile cerebral palsies were to some extent similar to the changes found in adults.

THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, May 14, 1906.

The President, Dr. Thomas E. Satterthwaite, in the Chair.

Rabies and Its Etiology.—Dr. Ira Van Gieson, after discussing the possibility of the occasional spontaneous development of rabies in dogs and other animals, spoke of a new, rapid, and certain procedure for the detection and study of the Negri bodies in hydrophobia. This method was particularly valuable in making the diagnosis of street rabies in dogs, as the whole procedure could be completed in two or three minutes. The method consisted of two steps: First, the preparation of a form of smear of the central nervous system; and, secondly, the application of a new staining solution. The important part of the method was the preparation of the smear technique, which was valuable not only for the study of rabies and the Negri bodies, but for the normal and pathological histology of the nervous system in general. The speaker had used this method for several years in the study of the nervous system, particularly in the investigation of the normal structure of the neuron bodies, and in their degenerative changes in a variety of nervous and mental diseases, and he was at present attempting to apply the technique in the study of the neurofibrils. If smears of the nervous system were made by the ordinary fashion of preparing blood smears, they were of little or no value. If, however, a portion of the gray matter, say the size of a bird-shot, was placed on one end of the slide, then covered with a cover-glass, gently squeezed out with the ball of the finger, and the cover-glass shifted across the slide, very beautiful preparations of the neuron bodies, with their dendritic and axonal prolongations, might be secured. The method was particularly valuable in recognizing pathological changes in the nervous system, and determining the plan of technical procedure for the subsequent study of sections. In its application to the study of the Negri bodies, these squeeze smears, dispensing with the time and trouble of preparing sections, might be fixed while moist for a few seconds in methyl alcohol, or dried in the air. The smears were then stained by pouring a few drops of the staining solution over them, and held over the flame until the dye steamed. They were then rinsed, dried in the air, and this finished the procedure. The stain was prepared as follows: Add to 10 c.c. of distilled water, two drops of a saturated alcoholic solution of rose anilin violet, and two drops of a saturated aqueous solution of methylene blue, diluted one-half with water. The Negri bodies took a distinctive deep crimson color, with their chromatin particles blue. Dr. Van Gieson then described and illustrated with charts the structure of the Negri bodies, and stated that this method, in the hands of Dr. Williams, of the Research Laboratory of the Board of Health, had added very materially to the knowledge of the structure and significance of the Negri bodies. He also referred to some experiments made in conjunction with Dr. Poor to determine the significance of these bodies. These experiments consisted in subjecting portions of the nervous system of rabid animals to various chemical agents, with a view to destroying either the bodies or the rabic virus, which could be confirmed by animal inoculation.

A Study of Seventy Cases of Brain Tumor.—By Dr. Arthur Conklin Brush of Brooklyn. (See page 215.)

Aphasia.—Dr. Edward D. Fisher read a paper on this subject, in which he said that aphasia was divided properly into motor and sensory, both functional areas of the brain being necessary for the acquisition of speech. A receptive center was necessary for hearing the spoken word, and also a motor center to translate the memory of words into active expression. Speech was synthetic; that is, while its acquisition was essentially through the hearing and motor centers, and these were probably the only necessary means, still, the sight of the written word, as we later acquired the power of reading and writing, aided largely in speaking, and in aphasia might be an avenue for the reacquirement of the impaired function. We could include as aids to speech also our general information of the nature of the subject or object to be spoken of. Motor aphasia, Dr. Fisher said, was not always absolute. Some few words or expressions might remain, as, for instance, yes or no; but frequently, in those cases, the answer to all questions, whether requiring a positive or negative reply, would be yes or no. A peculiarity of some of these patients, again, was their ability to sing some familiar song, correctly carrying the air or joining in a chorus, although unable spontaneously to speak more than a few words. This was evidently a purely mechanical process, various memory centers sending through association fibers impulses to the motor centers for speech. In many cases of motor aphasia incomplete in character, and associated with right hemiplegia, there was considerable amnesic aphasia, *i.e.* a loss of the memory of the names of things, with no impairment of the understanding of them when spoken. This was due, probably, to the involvement of the fibers in the island of Reil which had come from the first temporal convolution to the third frontal. The speaker mentioned an interesting instance of a certain small residuum of speech being left in a case of motor aphasia. The patient was a woman, about eighty, who could only say in reply to any question, although she understood it, "The Bishop to himself hath said." It was impossible to learn where she had obtained this expression. It was probably some vivid or last impression, heard or read just before the onset of a slight apoplectiform seizure. Agraphia, Dr. Fisher said, was almost invariably present in amnesic aphasia, showing the secondary and subsidiary relationship of writing to speech itself. It would be difficult to think of agraphia as other than motor, *i.e.* a loss of the memory of the necessary coordination of the hand muscles for writing. In word deafness we might have perfect power of speech, although the patient did not understand when spoken to. Still, in many such cases we had a form of paraphasia or jargon speech, which was not perceived by the patient, as he was word deaf. In paraphasia with a lesion in the motor or adjoining centers the speech might also be of this jargon type; but under those conditions the patient recognized it as such. The commonest form of aphasia was motor, with some amnesia and agraphia, the lesion involving the subcortical portion of the third frontal convolution, and the Island of Reil.

Dr. William M. Leszynsky said there was one point in regard to the subject of brain tumors that should be emphasized, particularly to the general practitioner; namely, that every patient, young or old, who complained of con-

tinuous headache, either with or without vertigo or vomiting, should be subjected to an examination of the ocular fundus. The importance of this was evident, for although optic neuritis did not occur in every case of brain tumor in the early period of the disease, it did occur, sooner or later, in from 80 to 90 per cent. He could recall a number of cases in which the patients were totally blind when they first came under his observation, the symptom resulting from an optic neuritis which was primarily due to a brain tumor. Dr. Leszynsky said he had seen six cases of brain tumor during the past year, and three of them had come to autopsy. Two of these cases were rather remarkable, and presented the following analogous features: The patients were intelligent young adults; both had frequent attacks of intense headache, vomiting, delirium, and convulsions; a high degree of bilateral papillitis accompanied by early, total, and permanent blindness; astereognosis, without any disturbance of general sensibility; absence of paralysis involving the extremities; only a slight, transient hemiparesis. The diagnosis of brain tumor involving the right hemisphere was made, but the exact location of the neoplasm could not be determined *intra vitam*. In both cases the tumor was found in the right lateral ventricle, and proved to be sarcomatous. Dr. Leszynsky said that in another case which was under his observation at present the patient was a girl of twelve years, whom he first saw with her physician the early part of last spring. She then showed all the indications of a brain tumor; a correct localization was made and an exploratory operation advised. After several months' delay, during which time the patient became totally blind, an operation was consented to, and a subcortical cyst was found involving the Rolandic area. Prior to operation this girl, in addition to her blindness, was completely paralyzed on the affected side of the body. Immediately following the operation the paralysis began to improve, and the only symptom that now remained was the blindness. In that case, the speaker said, if the operation had been done early, the patient's sight would have been saved. In speaking of brain tumor of traumatic origin, to which Dr. Brush had referred in his paper, Dr. Leszynsky said he recently saw a man who gave the history of having received a blow over the right temple with a man's fist two years before. The blow staggered him, but he did not fall. A few weeks later he began to complain of somnolence, with occasional attacks of headache and vomiting. When he entered the hospital he was blind, and an examination of the eyes showed choked disks. A diagnosis of tumor involving the right hemisphere was made, and an exploratory operation was under consideration when the patient suddenly died. At autopsy it was found that a spiculum of bone had broken off at a point just about an inch above the internal auditory meatus and had perforated the dura, and from this a large tumor had developed, which pressed upon the temporal and parietal lobes of the right side. The case would have proved an ideal one for operation. As to the treatment of brain tumor, the speaker, after referring to medication, said that in some cases lumbar puncture had given relief, while in others it had aggravated the pain, and even produced death. It could not be looked upon as a safe measure in these cases. The decompression operation, as practised by Cushing of Baltimore, was of distinct value in relieving the pressure symptoms, and even the optic neuritis. In dealing with cases of aphasia, Dr. Leszynsky said that a guarded prognosis should always be given as to a return of the power of speech.

Dr. Calvin F. Barber of Brooklyn said that, in operating on these cases, it rested with the surgeon whether to make a bone flap or remove the bone entirely. Both measures had strong advocates, and doubtless both had their advantages. Personally, the speaker said, he was in favor of removing the bone entirely, and leaving it out. This did no harm, as the uncovered section of the brain became well protected in the course of time, whereas one objection that might be raised against the use of the bone flap was that it frequently gave rise to necrosis. In the removal of tumors of the brain, Dr. Barber said, a sufficiently large section of bone should be removed to enable the operator to work safely. The removal of tumors that were circumscribed and favorably located was comparatively easy. Those located in the region of the medulla were the most difficult of access. The speaker said he did not consider it advisable in every case to incise the dura at the primary operation, and he could recall cases in which the mere opening of the skull brought marked relief to the patient. He did not have much fear of sepsis in these operations, and had never seen it. He agreed with Dr. Leszynsky that trauma was at times the causative factor of brain tumor.

Dr. J. Ramsay Hunt, in speaking of the diagnosis of tumor of the brain, emphasized the importance of other pathological conditions that produced the general and focal symptoms of central neoplasm. Among these he mentioned acquired internal hydrocephalus, syphilis, and toxic states of obscure nature. Nonne had recently called attention to the importance of this group of cases under the title of pseudotumor of the brain, and had recorded cases, with autopsy, in which no pathological lesions could be demonstrated which would explain the symptoms observed during life; also cases which were clinically tumor, but in which the symptoms cleared up entirely, and where syphilis could be ruled out. In this connection, Dr. Hunt said, he wished to call attention to chronic progressive softening of the brain, two instances of which had come under his observation. In one, a localized parietal arteriosclerosis, situated at the junction of the internal carotid, middle cerebral, and posterior communicating arteries, had induced a gradual and successive obliteration of the central perforating vessels of the anterior perforated space, with small areas of necrosis, cavity formation, and sclerosis in the corpus striatum, optic thalamus, and internal capsule. The successive obliteration of the central vessels had occurred in such a way as to produce a hemiplegia, with sensory irritative symptoms of very gradual development, involving, first, the face, then the arm, and later the leg, simulating the progressive lesion of a tumor. In the other case a progressive hemiplegia developed on the right side, with all the general symptoms of brain tumor, including optic neuritis. Post mortem, the vessels of Willis were found free from sclerotic changes. The small, multiple foci of softening which were present in the internal capsules and basal ganglia on both sides were referable to arteriosclerotic occlusions of the central perforating vessels. The optic neuritis might have been due to diabetes, which was present. As regarded surgical intervention in cases of cerebral tumor, Dr. Hunt thought that an exploration was not only justifiable, but indicated in all those cases in which the probable localization could be determined, and if the cerebral or basilar situation of the growth did not preclude absolutely the possibility of removal. Even if clinically the symptoms indicated a subcortical growth or deep-seated tumor, but with focal symptoms referable to the superior or lateral aspect of the brain, an exploratory procedure would be advisable, for even if the growth could not be extirpated, the relief of tension would tend to favorably modify the general symptoms, and preserve the optic nerves. In cases of nonlocalizable and inoperable brain tumors the speaker thought that the palliative operation should be performed earlier and more frequently than was now the custom. Cushing's procedure of decompression, forming a temporal or occipital muscular flap to prevent the formation of a hernia cerebri, was a most admirable one, and should be accompanied with but little danger.

Dr. L. Pierce Clark emphasized the importance of having every case of brain tumor operated on before pronouncing it hopeless. During the past year the speaker said he had seen three cases in which a material improvement, if not an actual cure, might have been effected by surgical interference. The ultraconservatism that had been thus far

shown in dealing with these cases from a surgical standpoint was no longer justifiable. Cerebellar tumors were not as inoperable, at least in the early stage, as had been heretofore held. In the medical treatment of syphilitic gumma of the brain, Dr. Clark said, too much stress had been laid upon the value of the iodides in preference to mercury; the latter drug should be pushed to the extreme before the iodides were given.

Dr. C. G. Am Ende said that a number of years ago he experimented quite extensively with protozoa under the microscope. In conducting these experiments he obtained very reliable results by using a solution of one ounce of boric acid in equal parts of alcohol, water, and glycerin. This left the most delicate tissue uninjured, but destroyed the life of the protozoa.

Dr. William B. Noyes said that in a case he had observed about six years ago, in which all of the classical symptoms of rabies were present, the autopsy showed a massing of the round cells in the capillaries of the cord. This was before the discovery of the Negri bodies.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

Stated Meeting Held April 17, 1906.

Dr. Warren Coleman, Chairman.

An Unusual Case of Gonorrheal Endocarditis.—Dr. Morris Manges reported this case, and showed the specimen. The patient was a married woman, twenty-five years old, who was admitted to Mount Sinai Hospital on February 8, 1906. Her family history was negative, with the exception of the fact that her husband gave a doubtful history of venereal disease. The patient had measles when she was five years old, and typhoid fever seven years later. Her habits were good. She had been married three and a half years, and had one living child; none dead; vaginal discharge during past year. Her present illness was of two weeks' duration. It began with fever, headache, malaise, and chilly sensations, together with swelling of the left hand and wrist. The involved joints had all the characteristics of gonorrheal joints. The swelling steadily increased, so that on admission the patient was unable to use the hand. No other joints in the body were involved. The physical examination was negative, with the exception of a loud, blowing low-pitched systolic murmur at the apex, transmitted to the axilla and back, and upward to the base. There was also a soft systolic murmur accompanying the first pulmonic sound, and the second pulmonic sound was accentuated. The pulse was normal. The spleen could not be felt. Urethral smears, cultures, and spreads were negative for gonococci. The urine was negative. Blood cultures were negative. On February 28 the patient was distinctly worse. She was delirious and had a septic appearance. The tongue was dry; there was marked pallor. The heart murmurs were harsher and more distinct. The patient died on March 2, 1906. The autopsy proved the cause of death to be an acute gonorrheal endocarditis. The right heart showed nothing abnormal. On the posterior flap of the mitral valve was a large soft mass the size of a cherry, in the interior of which was a small collection of pus. Especially remarkable was the fact that the entire heart was sterile except the small collection of pus in the interior of the large vegetation, in which Dr. Libman found characteristic gonococci. This will explain why the blood cultures were negative. Two other facts are interesting, one is that no gonococci were to be found in the urethral or original discharges. The other was that the diagnosis of gonorrheal rheumatism could not be doubted clinically in spite of these negative findings because the joints were so characteristically gonorrheal. The Bier treatment was used and its effects considered bad in this case.

A Case of Primary Sarcoma of the Stomach.—Dr. Manges reported this case, with specimen. The patient was a woman, nineteen years old, who was admitted to Mount Sinai Hospital on March 14, 1906. Her family history was negative. The patient had typhoid fever eight years ago. After she had been subjected to great privations during the recent trouble in Russia she began to complain. Her present illness was of two months' duration, and began with epigastric pain and vomiting. Since that time she had suffered from pain in the left hypochondriac and epigastric regions. She vomited once or twice daily. The abdomen was rounded, and there was tenderness in the left inguinal region. The lumbar muscles were somewhat rigid, more marked on the left side. There was a mass like an enlarged spleen, extending well beyond the middle line. On March 18 the patient complained of epigastric and general bodily pains, and vomited a brownish material. The appetite was poor. The stool contained a heavy trace of blood; the vomitus contained no blood. On the following day the patient vomited some undigested food which was blood flecked. On March 26 she was much worse; vomited small greenish purulent masses. The moderate temperature now rose to 103°, there was great tenderness in the upper abdomen; peritoneal rubbings could be heard over the tenderness and the mass in the upper abdomen was less perceptible on account of its tenderness. The following day she became worse and an operation was decided upon. The abdomen was opened in the median line, allowing an escape of bloody serum from the peritoneal cavity. Further inspection showed a large tumor, moving with the respirations, and adherent to the parietal peritoneum. It was hard, and sprang from the greater curvature of the stomach. The case was regarded as inoperable, and the abdomen was closed. A section removed from the growth was submitted to Dr. Mandelbaum, who pronounced it a sarcoma. The patient died on March 27, 1906.

Dr. Harlow Brooks referred to the difficulty of recognizing primary sarcoma of the stomach during life. In the specimen shown by Dr. Manges, the degree of involvement was greater than in any case he had ever seen. Lymphosarcoma was the most common variety of the disease met with in this region.

The Bacteriology of the Blood in Sepsis.—Dr. Robert J. Wilson said that Canon distinguished three stages in the course of sepsis: 1. In the first stage, the bactericidal power of the blood was still unimpaired. The pus organisms might get into the blood, but were rapidly killed off, so that in general they were not demonstrated by cultures. 2. In the second stage, the bactericidal power had decreased; the organisms which entered lived rather longer, and were usually more readily cultivated, though, as a rule, only in small numbers. 3. In the third stage the bactericidal power had been used up; the bacteria multiplied and were readily demonstrated even in small quantities of blood. This last was called septicemia in contradistinction to bacteriemia, which was merely the presence of bacteria in the blood. In speaking of the frequency and severity of sepsis, Dr. Wilson said that the blood infections with streptococcus took first place. Others frequently met with were the staphylococci, pneumococci, and the colon bacilli. The streptococci gained an entrance into the blood either through the lymphatics or directly. Formerly, a large number of cases were met with in which the bacteria were carried into the blood stream by broken down infected thrombi. That was not nearly so frequent now. If only a few organisms got into the circulation, the bactericidal power of the blood might be sufficient to kill them off. Very likely that happened very frequently, and there might not be any appreciable external lesion infection through the tonsils. The localization depended on the anatomical conditions, and also on the receptor apparatus of the tissues. Thus, the streptococci seemed particularly

partial to joints, serous membranes, and kidneys. Of course, the organ which offered the least point of resistance would be invaded. A positive blood culture possessed both symptomatic and diagnostic value. It showed the extent of the bacterial development in the affected area, and, above all, it showed that that area was no longer able to control the streptococci. It also made the existence of metastases more probable. So far as metastases were concerned, Lenhartz had published the following figures: Of 160 cases of streptococcus sepsis, 65 per cent. were without metastases and 35 per cent. were with metastases; of 22 cases of staphylococcus sepsis, 5 per cent. were without metastases and 95 per cent. with metastases; of 20 cases of pneumococcus sepsis, 75 per cent. were without metastases, and 25 per cent. with metastases; of eight cases of colon bacillus sepsis, 78 per cent. were without metastases, and 22 per cent. with metastases. In connection with these figures it should be borne in mind that the development of metastases was more probable with increasing duration of the disease. In 29 cases of puerperal sepsis, of which seven recovered, Lenhartz found the streptococcus twenty-five times, the colon bacillus twice, the proteus once and the gas bacillus once. Canon had published a number of staphylococcus findings in puerperal cases; these were next numerous, in his experience, to the streptococci. Lenhartz had found that a puerperal sapremia was often accompanied by a genuine bacteriemia.

The Puerperal Types of Sepsis.—Dr. William S. Stone read this paper. (See page 213.)

The Medical Aspects of Bacteriemia, with Special Reference to Diagnosis.—Dr. Harlow Brooks said that a distinct etiological focus could be discovered in the majority of cases of bacteriemia; in many, an abscess, an infected wound, or a thrombosed vessel was found, which, taken in connection with the temperature curve, the pulse and the blood findings, as well as the history and general picture of the case, rendered a probable diagnosis a practical certainty. It was particularly those cases, however, in which treatment was relatively obvious that did not fall to the lot of the physician, but came within the realm of surgery. Such instances of bacteriemia, therefore, were of but little interest to the physician, who was called upon to face quite different and infinitely more obscure aspects of the disease. The conditions which were most frequently confused with medical bacteriemia were certain specific hemic infections, such as enteric fever and miliary tuberculosis; also, some of the more obscure forms of pneumonia, malaria, osteomyelitis, rheumatism, and an occasional instance of myeloma. In the recognition of medical bacteriemia, a careful history of the case was of primary importance. The general appearance of the patient, an examination of the skin, the presence of local lesions, etc., often led to the correct diagnosis. The spleen was enlarged in most cases of bacteriemia, and was often palpable, together with hepatic swelling and tenderness. The cardiac area, as a rule, was somewhat increased, particularly in those cases complicated by endocarditis. In typical cases the pulse rate corresponded fairly well with the degree of temperature present at the same time, but in some cases a slow, full pulse was found with the pyrexic stage. Although the presence of temperature was one of the most significant and constant indications of bacteriemia, the precise manifestation of this symptom was among the most irregular of the disease. The typical temperature curve of most infected cases showed a rapid rise, usually in the afternoon, with an equally speedy fall beginning very soon after the highest point of temperature had been reached. The highest temperature might occur in the morning, or at any other time. Occasionally, periods of pyrexia were separated by considerable apyrexic epochs, or they might be preceded by a short space of subnormal temperature. In some cases, particularly where endocardial infection was present, regular paroxysms closely simulating those of malaria might be seen, preceded oftentimes by chill, pains in the muscles, tenderness over the superficial bones and muscles, and succeeded by profuse perspiration and somnolence. Temperature variations were very slight in a certain number of cases, even in some of great severity. The speaker said he had been unable to trace any definite connection between either the severity of the disease or the temperature curve and the particular microorganism responsible, even when tests as to virulence had been made, and he was firmly convinced that the clinical aspects, in most instances, were more dependent on the reaction of the body organism against the infection itself than on the special microorganism and its degree of experimental virulence. Albumin and casts were found in the early stages of most instances of the disease. They might persist throughout, especially when true renal infection took place. Blood, mucus and renal epithelium might also appear. Bacteriological cultures of the urine, as well as the bacterial examination of a discharge of any nature whatsoever, might furnish data of a highly instructive character, but the careful examination of the blood unquestionably furnished the most absolute data for the diagnosis of bacteriemia. For satisfactory results, considerable quantities of blood were usually necessary. Furthermore, the culture media employed should be abundant. Several cultures were oftentimes necessary before the true nature of the condition could be demonstrated. He believed that positive results were secured with much greater certainty when the cultures were taken with the rising temperature, and were the more favorable the nearer the summit of the temperature wave was approached. Leucocytosis, while usually present, was by no means invariable, and was frequently absent, especially in severe cases of overwhelming infection. On the other hand, leucocytosis might be absent or very slight in severe, though favorable cases. As a rule, however, the number of leucocytes corresponded in general to the relative number of bacteria present in the blood, though in some instances localized and well-encapsulated septic foci gave rise to very pronounced leucocytosis. Hypoleucocytosis was present in certain cases, notably in tuberculous or typhoidal infection, in which the condition was usually associated with a relatively high percentage of mononuclear elements. In nearly all instances of bacterial infection of the blood, a falling hemoglobin percentage was demonstrable, even in those advancing to recovery, though not yet convalescent.

The Surgical Types of Sepsis.—Dr. John A. Hartwell, in discussing this phase of the subject, said that if one consulted the bacteriological reports from the cases found in any general surgical ward, a vast majority of them showed either the *Streptococcus pyogenes*, or one of the staphylococcus groups, occurring alone or in combination with each other, or with other organisms. These infections presented themselves in a mild or severe form, whether they were superficial or deep, so that the only safe rule was to consider every infection with the streptococcus, and to a lesser degree with the various staphylococci, as having latent possibilities for great damage. Any other course invited disaster. We were all familiar with the superficial abrasion or prick, which seemed so innocent that to dignify it as serious appeared an overcaution, but which in twenty-four hours might threaten limb, or even life. As yet, we were in total ignorance of the underlying factors which determined when such a thing was to happen. To say that its occurrence depended on the virulence of the infection, as compared to the resistance of the individual, gave no real information, because both of the factors in that formula were at present indeterminate, until the course of the case had determined them. The speaker mentioned a case of severe infection resulting from a lacerated wound over the dorsum of the thumb, where more than a week elapsed from the time of the original injury before the tissues established sufficient reaction to produce any pus. Prior to that, the bacteria grew unopposed in all directions. The infection was one of strepto-

coccus. Ludwig's angina, the acute infection starting within the submaxillary capsule, and usually terminating fatally, was another example of the same nature. In such cases, nothing indicated this lack of resistance until the damage had been done. The surgeon was seldom called on to treat any condition where a ripe experience and a well balanced judgment were so requisite as in determining the probable ratio between virulence and resistance, and the treatment depended on its answer. We know that any tissue that was subject to an attack from pyogenic bacteria showed, first, a congestion of the blood-vessels; second, an exudation of its lymph fluid; and, third, a marshaling and proliferation of the phagocytes. Those were the factors that made up the entity called resistance, and upon their successful establishment the tissue was prepared to fight the infection. The idea had long prevailed that the congestion or hyperemia was a deleterious condition, and one to be combated, and the first impulse usually was to adopt means to "reduce the inflammation." What was the significance of this congestion? Was it a sign of weakness on the part of the tissues, or was it a sign of strength? Did it indicate a surrender, or a calling out of the tissue defense? Judged purely from the side of reason, and leaving out of consideration the teaching of experience, one was at a loss for proof that it was not a conservative rather than a destructive process. Unless the pressure from the exudate became so great as to threaten a stoppage of the actual flow of blood through the veins, or the bacterial invasion into the capillaries was sufficient to do that, the mere presence of the excess of blood in the parts seemed harmless. On the other hand, there was evidence that this congestion was of benefit. Bier and others, noting the fact that pulmonary tuberculosis was rare in persons suffering from cardiac lesions that produced pulmonary congestion, had suggested the production of a passive congestion in the treatment of surgical tuberculosis. Experience had amply justified the soundness of that principle, and of late it had been applied, with modifications, to the pyogenic infections. The second stage of defense, the pouring out of the exudate, followed as a result of the congestion. All observers were now agreed that the active combatants against infection were the leucocytes, and the polynuclear leucocytes probably took the lead. Sondern, however, had called attention to the fact that when the total leucocytes were increased in a less degree than the polynuclear, the prognosis was not good, and Gibson, working on that hypothesis, followed a large number of cases of surgical infection, and found that the prognosis bore a very close relation to the relative leucocytosis and the polynuclear-cytosis, a preponderance of the latter being unfavorable. No explanation of these findings offered itself. It was probable, however, that much of the battle was fought by the fixed cells of the part, and that the conditions found in the blood elements were more an expression of the way in which the fight was going than a representation of the fighting force.

Dr. Herman J. Boldt said there was perhaps no phase in the specialty of obstetrics and gynecology that had interested physicians more than septic infections. Since the discovery of Semmelweiss that puerperal fever was dependent upon definite, and, as he believed, avoidable causes, attention to this subject had steadily increased. Although great strides had been made in the study of this subject, it was likely that much time would still elapse before a unanimity of opinion was reached on the many mooted points. It seemed that a much more rapid progress should have been made in the study of puerperal infections, when it was considered that Semmelweiss proved that after it had become compulsory, through his influence, that the hands should be thoroughly disinfected before the examination of any pregnant or puerperal woman was undertaken in the hospital in which he was assistant, the mortality rate at once changed as from night to day. For example, in 1846 before hand washing, as recommended by Semmelweiss, was practised, the mortality among 3,354 women was 459. In 1848, after chlorine hand disinfection had become compulsory, the mortality among 3,356 women was only 45. Numerous forms of microorganisms had been found in puerperal patients: streptococci, *Staphylococcus albus* and *aureus, Bacterium coli, Bacillus aerogenes capsulatus, diplococci* and *diplobacilli.* Investigations had shown that genuine streptococci lived in the vagina of clinically perfectly healthy women as innocent saprophytes; that during their ascent their character might become entirely changed, their virulence being increased through changes in the fostering soil during labor or at the beginning of the puerperium. Theoretically, the most rational method by which to combat septic infections was by means of serum therapy, analogous to the treatment of diphtheria with antitoxin, but, unfortunately, nearly all fatal cases of puerperal infection were examples of mixed infection. The most recent contribution on the prognosis of puerperal fever, as determined from examinations of the blood, had been made by Kownatzki of Berlin, from studies in the Charité. His conclusions were as follows: 1. Favorable prognosis, if there were no deterioration of the neutrophile blood picture, or only a slight one; the presence of eosinophile cells. 2. Unfavorable prognosis if the leucocytosis was more than 50,000, with serious deterioration of the neutrophile blood picture; absence of eosinophile cells; decided diminution of the number of red blood corpuscles. 3. An improvement was shown by betterment of the neutrophile blood picture and an increase of the eosinophile cells. 4. Retrogression was manifested by a deterioration of the neutrophile blood picture and diminution or disappearance of the eosinophile cells. 5. Those cases were prognostically absolutely uncertain in which there was an appearance of poikilocytosis combined with polychromasia, and nucleation of the red blood cells.

Dr. John B. Walker said his hospital experience was in accord with that of others to the effect that cases of staphylococcus infection were less serious than those in which the streptococcus was found, and that surgical measures undertaken for the relief of the former were proportionately more satisfactory than for the latter. In the streptococcic cases, as Dr. Hartwell had pointed out, more was to be gained from general systemic treatment than from operative interference.

Dr. Ellice McDonald said that streptococcus infection in the puerperium differed from all other streptococcus infections in that it occurred in organs whose anatomical relations and blood supply were temporarily altered. This was of as great importance in determining the extent of the infection, as was trauma in favoring its origin. The lessened resistance of the pregnant woman to infection was also a predisposing factor. Infection with this form of organism differed from many other infections, because the human blood serum was not supposed to acquire bactericidal properties. The destruction of the microorganisms and the relief from the infection, was brought about by phagocytosis. If the leucocytes were active and fulfilled their part, the infection was overcome; in other words, if the opsonin was sufficiently increased, the streptococci were destroyed. In the study of any infection, it was of importance to understand the location and character of its lesions. The most common lesion of puerperal infection was an endometritis, and with it was usually associated a periuterine thrombophlebitis or lymphangitis. Grossman, in a study of 51 cases dying from puerperal infection, found periuterine thrombophlebitis alone in 14 instances, and associated with lymphangitis in 13 other instances. Lymphangitis was found alone in 24 instances. Trendelenburg found thrombophlebitis in 21 of 43 fatal cases of puerperal infection. In 14 cases, it was bilateral and in only four was it associated with lymphangitis. This led him to advocate his operation of ligation of the uterine and

ovarian veins in such cases. From this focus, the infection may extend through the lymphatics of the broad ligament, and cause a peritonitis. Streptococcus infection alone very rarely affected the tubes; when a pyosalpinx occurred, it was usually due to the gonoccocus. Puerperal streptococcus infection did not cause marked anatomic alteration in the pelvic structures, but was of the nature of an acute cellulitis and lymphangitis, as this infection was elsewhere. The broad ligaments became thickened, and the cellular tissue was edematous and infiltrated. From this, it might extend to cause a peritonitis, which did not come from the tube, but through the lymph channels. This peritonitis was often general in character. General septicemia was an infrequent termination of puerperal infection; it might be shown as pericarditis, septic pneumonia, or septic pleurisy. Pyemia was, as a rule, a late evidence of streptococcic infection, and sometimes occurred months after an attack of puerperal infection. The abscesses were usually located in the broad ligament, and not infrequently pointed anteriorly. The diagnosis, then, of puerperal infection depended upon the presence of constitutional symptoms of infection, the discovery of streptococci in the genital canal, and the location of the lesion. Among the more important of the constitutional symptoms was Mahler's *Klettersymptom*, or rapid pulse. The presence of streptococci in the genital canal was not alone sufficient evidence of puerperal infection. Pathogenic microorganisms often existed harmlessly in the lochia. Before any operative measures were undertaken, the course of the infection must be thoroughly understood and the lesion recognized. The futility of curettage in thrombophlebitis and lymphangitis was readily recognized. Its only effect was to stir up the infection, make new raw surfaces, and thus open new portals for the entry of the microorganisms. Celiotomy in cases of peritonitis was at the best only a palliative measure and neglected the condition of the broad ligaments and uterine veins. Of local measures, the most important was uterine packing. This seemed to have a salutary effect. Iodoform gauze was most commonly used, but why such a poison, without any antiseptic qualities, should be used was beyond comprehension. A 3 per cent. quinine gauze offered a very convenient substitute, excelling iodoform in cheapness and antiseptic qualities. Quinine was an antiseptic which held a place midway between bichloride of mercury and carbolic acid. It possessed no poisonous qualities and it was easily prepared. Webster's glycerine and formalin gauze was better than iodoform gauze. Antistreptococcic serum required a further trial in the treatment of this infection, more particularly on account of the favorable reports of English obstetricians with regard to the polyvalent sera. In dealing with septic involvement of the peritoneal cavity, Dr. McDonald said celiotomy was, at best, only palliative. He advised simply opening the abdomen and draining, after Murphy's method, with rubber tubes. The abdominal cavity should not be irrigated. Rectal salines, given by means of the gravity bag, and continued from one to four hours, were an important aid both in the treatment of the peritonitis and of puerperal infection generally. The cardinal principles in the treatment of puerperal infection were the absence of meddlesome surgery, when no definite lesion presented itself, and the endeavor to improve the patient's general strength, so that the constitutional defenses to the infection might be increased.

Dr. Manges said that attention had been called to the similarity between pseudocardiac murmurs and those met with in ulcerative endocarditis. Whether the former were due to abnormal muscular action or to a hemic condition or to some unknown factors in the pericardium was still open to question. The criticism was made that in the diagnosis of ulcerative endocarditis too much stress was laid upon the murmur and too little upon the presence or absence of petechiæ and other phenomena which accompany that condition. In regard to the Bier method of treating inflammatory conditions of the joints, to which Dr. Hartwell had referred, Dr. Manges said he had resorted to it in his case of gonorrheal endocarditis in order to relieve the swelling of the hand and wrist. Instead of relieving the condition, it gave rise to intense pain, and the speaker said he regarded the method as not only unsatisfactory, but as harsh and cruel.

Philadelphia County Medical Society.

At a stated meeting held May 9 Dr. Hilary M. Christian presented a communication entitled "Hematuria of Renal Origin." He pointed out the several conditions most commonly responsible for hemorrhage from one kidney, namely calculus, tuberculosis, neoplasm, nephritis, but he dealt especially upon the disorder unattended with pain and apparently of functional origin and designated essential hematuria. Various explanations of the affection have been given, but none is entirely satisfactory. By some it has been compared to hemophilia, while by others it has been considered angioneurotic. Dr. Charles P. Noble read a paper entitled "Fibromyomata of the Uterus: A Study of One Hundred Consecutive Cases Treated by Hysterectomy." He undertook an estimate of the gravity of fibroid tumors of the uterus by an elaborate study of the complications and degenerations encountered in a consecutive series of 2,274 cases from several sources, in addition to his own personal experience. Of the entire number complications were present in 1,553. From the statistics a conservative estimate may be made that 15 per cent. of women having fibroid tumors of the uterus would die without operation as a result of degeneration in the tumor and complications present in the uterus. Adding complications outside of the tumor and uterus the estimate deaths would be increased by from 15 to 25 per cent. The frequent coincidence of carcinoma of the uterus with fibroid tumors was referred to. The conclusion was considered inevitable that fibroid tumors of the uterus predispose to the development of carcinoma of the body of the uterus and probably also to carcinoma of the cervix. By reason of the foregoing conditions early operation is advised as a life-saving measure, the mortality from the operation being less than 5 per cent. in competent hands, as against the much higher death rate in cases not operated on. There is room for difference of opinion with respect to small subperitoneal fibroids causing few or no symptoms. Unless the future shows that the liability to carcinoma is the same from this type of tumor as from others it may be proper to continue the present policy of advising expectancy. All other fibroid tumors of the uterus should be removed when discovered, unless in the particular case there exist good grounds to the contrary.

Treatment of Cutaneous Sarcoma by Roentgen Rays.—Vincenzo Chirivino has made use of the Roentgen rays in the treatment of a case of cutaneous sarcoma that was multiple and pigmented, with good results. He recommends its use in such cases when the lesion has not become generalized and extended to the internal organs. The rays seem to have a better effect on sarcoma than on epithelioma, contrary to the general opinion, which is that the rays have selective action on epithelium. The lesions treated by the author consisted of very abundant vascular elements, amounting to vascular lakes, with a cavernous tissue about them, with fragile vessel walls and cells consisting of young elements, of new formation and low vitality, especially susceptible to the action of the *x*-ray. The application should be made only to localized nodules.—*Giornale Internazionale delle Scienze Mediche.*

* No reciprocity recognized by these States.
† Applicants should in every case write to the secretary for latest details regarding the examination in any particular State.

Illinois.—After 1910 this State will cease to recognize medical colleges that do not require in the entrance conditions at least nine months' work in biology, botany, and chemistry in a high school.

Iowa.—The State board of medical examiners has been enjoined from arbitrarily annulling the certificate of a licensed physician in this State. The District Court for Polk County granted a permanent injunction restraining the board from canceling the certificate of the plaintiff.

Texas.—Effort is being made to secure a new Medical Practice Act. Its object is to create one board of medical examiners for the examination and licensing of all physicians, surgeons, and obstetricians; to prescribe their qualifications; to provide for their proper registration, the revocation of their licenses for flagrant offenses, and to fix suitable penalties for illegal practice. The present law, according to the *Texas State Journal of Medicine,* is weak or deficient in many respects.

Washington.—Several would-be practitioners of Washington State who are unable to secure licenses to practise because they cannot produce the diplomas of an authorized medical college required by law have commenced a suit in equity against the State medical examining board, the president of the State Medical Association and the president of the King County Medical Association in the federal court at Seattle, contending that they are denied their constitutional rights. The court is asked to declare that all of the statutes regulating the examination of surgeons and physicians be declared unconstitutional and void on the ground that the provision requiring the possession of a diploma is class legislation.

Pennsylvania.—As a result of the recent examination of applicants for license to practise medicine in the State of Pennsylvania licenses were granted to 345 graduates, of whom 17 were women.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending August 4, 1906:

	Cases	Deaths
Tuberculosis Pulmonalis	406	157
Diphtheria	159	17
Measles	144	10
Scarlet Fever	56	4
Smallpox	—	—
Varicella	8	—
Typhoid Fever	133	17
Whooping Cough	57	12
Cerebrospinal Meningitis	14	6
Malarial Fever	.....	.....
Totals	977	223

An Exception to Colles' Law.—W. A. James reports this case. The patient, a woman thirty-nine years old, when first seen by the writer had an ulcer on the areola of the right breast. There was a large tender gland in the axilla, as large as a bantam's egg. The patient's baby had bitten her some days before. The wound healed in about five days, but seventeen days after the bite a blister appeared at the old wound, which in three days broke and became painful. Rapid ulceration set in and a week later the patient had a typical roseola rash on the chest and back; the hair fell out; there was hoarseness, mucous patches appeared on the inside of the cheek, tongue, and lips; pain in the jaws, some bone pains, tenderness over the sternum, and general glandular enlargement developed. Mercury was begun, and a few days later a papulo-squamous rash appeared on the legs and arms especially. A superficial reniform ulcer developed on the right tonsil. The baby also showed definite signs of syphilis. All of the medical men who have seen these cases agree that the mother is a secondary syphilitic, and that the child is a congenital syphilitic. The writer holds that this case is an undoubted exception to Colles' law.—*Intercolonial Medical Journal of Australasia*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon General, Public Health and Marine Hospital Service for the week ending August 3, 1906:

MEDICAL EDUCATION AND MEDICAL PROGRESS.*

BY GEORGE H. GRANT, M.D.,

RICHMOND, INDIANA.

MEDICAL education has a traditional history as old as the earliest record of the thoughts and acts of men. Fragmentary, disconnected, valueless except as ethnological curiosities as these records are, they are found the world over, in the hieroglyphics of the Egyptian pyramids, in Babylonian and Greek inscriptions on ruined temple walls, on Aztec altars, and in the sign writings of savages.

In this dim voiceless past the healing art in every quarter of the globe was a part of the mysticism of the priesthoods, having no existence as a separate profession. Knowledge of the charms and incantations, as well as of material remedies and surgical procedures, was revealed in great secrecy by the aged priests to the novice who had proven his worthiness to receive the holy mysteries, or was imparted by fathers to their sons so that certain families would control one entire specialty. But wherever civilization advanced, the mysteries and incantations were gradually worn away by the attrition of common sense. While the practices remaining were crude, very often dangerous, and almost invariably based on illogical premises, due to a lack of anatomical and physiological information, they had the merit of being reasoned out from the total of knowledge then at hand, minus the mysticism which was the foundation of the priestly system.

But medicine became a pursuit *per se* with Hippocrates, one of the greatest teachers the world ever knew; so great, indeed, that for centuries his writings inspired all medical literature, and his teachings sufficed for a changeless system of practice.

And with the brilliant Galenus, skilled anatomist, able surgeon, and careful generalizer, the profession lost many of its remaining errors, and took on a fundamental nature which may fairly be called philosophy. Seven hundred years after the death of Galenus, the Persian sage, Avicenna wrote his "Canon of Medicine," based on the systems of Hippocrates and Galenus, and in the far east the Canon is to-day revered and followed. Influenced by various causes, perhaps by personal selection or through the eloquence of some teacher, or on account of the traditions of a school of medical philosophy, the systems of Hippocrates and Galenus had equally their partisans throughout the civilized world. And so the profession was divided and remained content to quarrel through the intellectual gloom of the Dark Ages, blindly following the one or the other master mind with no application of personal observation, and bitterly denouncing in ponderous Latin theses the adherents of the other school.

But a period of mental unrest, of awakening and illumination came. Columbus sailed away and came back with a golden empire for mighty Spain, and the sails of the Argonauts of every nation caught the westering winds. Civilization's horizons had infinitely broadened. The little black friar of Erfurt had nailed his defiance to Rome on the doors of Wittenberg's town hall and had set in motion the mighty Reformation.

Through all this turmoil of political, commercial, and religious upheaval, medicine as well shared in the world movement. A Swiss chemist, surnamed Bombastus, had a son who had taken up the study of medicine. By an odd combination of his various names, converted into Greek and Latin, he became known as Paracelsus. Never did a son deserve a father's patronymic as did he. Through the assistance of a powerful friend he had the fortune early in his professional life to deliver a course of medical lectures at Basel.

At the very outset of his career he betrayed his ill-balanced methods which so soon resulted in his downfall. On the occasion of his first lecture he ostentatiously burned the almost sacred works of Hippocrates and Galenus and introduced a system of medical and surgical works of his own, which, he announced, contained the entire scientific information in all branches of these arts. But "he was one of the first physicians to profit by a mode of study which is now reckoned as indispensable. . . . . He broke away from tradition and delivered his lectures in German, not in Latin. They were expositions of his own experiences, his own views, his own methods of curing, adapted to the diseases that afflicted the Germans in the same year, and they were not commentaries of the text of Galenus or Avicenna." On account of this departure from the time-honored method of lecturing in Greek or Latin, and because of his introduction of his own personal method, and doubtless, too, because of his successes, he was denounced, despised, and finally killed by his professional enemies. The special value of Paracelsus' work, in additon to having contributed some minerals to the pharmacopœia, was in teaching the application of an individual treatment to each case, based on its particular study, and not merely following the unvarying dicta of an antiquated philosophy. The unfavorable opinion of Paracelsus usually held by historians was not shared by Robert Browning. He idealized Paracelsus, making his life and work typify renunciation. Less boastful are the noble lines in which Browning makes him say, "I profess no other share in the selection of my lot than this my ready answer to the will of God, who summons me to be his organ, and appoints no less the way to praise than the desire to praise, and such praise is best attained when man attains the greater welfare of his kind."

Gradually through the years that stretched out into centuries, the idea of personal research and observation permeated and directed medical instruction. Through this developmental period that comes down to this very day, standing out like great sun-

*Presidential address delivered before the Indiana State Medical Society—1906.

illumed headlands above the foggy levels of mediocrity and nonachievement, are such names as Paré, Sylvius, Harvey, Morton, Lister, Pasteur, Koch. These and others that time prevents naming have put the solid foundations under medical education of to-day.

In a comparatively young nation like ours the opportunites for college education, as preliminary to the medical course, were, until the last few decades, either not considered or obtained with great difficulty. For many years medical educators in the United States felt the humiliation of the unfavorable estimate in which their student bodies were held abroad. Within our own borders the older, wealthier, and better organized institutions of the Eastern States discredited medical graduates from the West or South. This discrimination was not due to a spirit of Phariseeism or aloofness as much as to a proper enough comparison of the preliminary educational requirements, plus the thoroughness of the course in medicine existing in the older and in the newer institutions. No more helpful thing could possibly have happened to the obscure little Western school than the realization by its faculty of the entire propriety of this attitude of the powerful colleges, for a certain percentage of the teachers in these small schools were graduates of the greater institutions, and therefore they earnestly labored to elevate the standard and strove to equalize the premedical as well as the medical requirements in the East and the West.

Almost every medical man here has seen the fruit of these efforts, first in a more comprehensive medical course of two years in college and a year with the preceptor, then added entrance requirements and three years in college, and finally four full years in college with a preliminary education equal to that of a high school as a minimum requirement of every matriculant for a medical degree, as is the case in Harvard and Johns Hopkins.

While at present the Indiana State Board of Medical Examination and Registration does not require a college degree from matriculants, it is a matter of pride to note that our State is one of six that requires a preliminary examination over work equivalent to that of a four years' commissioned Indiana high school of all matriculants who have not a high school diploma. The board announces a considerable diminution in the number of prospective medical students, an abundant evidence that the student body and graduates are of a greatly improved character,

But the most important work of the board has been on behalf of interstate reciprocity. Aided by Michigan and Wisconsin, Indiana has done more in this matter than all the licensing boards of the United States combined. In his farewell address to the profession in the United States, Dr. Osler said: "In this country reciprocity between the State licensing boards remains one of the most urgent local needs. Given similar requirements and examinations, practically of the same character, with evidence of good reputation, the State Board should be given power to register a man on payment of the usual fee. It is preposterous to restrict in his own country, as is now done, a physician's liberty. . . . I would urge you all most strongly to aid the movement now in progress to place reciprocity on its proper basis."

This board has done excellent work, when the difficulties they have encountered are considered, in ridding the State of quacks and illegal practitioners. First and worst of these difficulties is the jury. Acquittals in the most flagrant violations of the law are obtained through the sympathy of the unthinking laity for what they consider persecution. But lack of funds, weak spots in the statute, and apathy on the part of the profession are among the other obstacles that hamper their work. Better men because of their superior mental training are studying by better methods a far better system of medicine, and if the result be not better practitioners, the fault must lie with the sudent.

The possession of a degree and a license to practise medicine does not justify the graduate in believing that his medical education is complete. At his earliest opportunity he should join the County Medical Society and take an interest in the district and State medical associations. Society work of this kind will broaden a man by bringing him in contact with older practitioners, hearing and discussing their views, and acquiring a more friendly relation with these brothers in medicine. In effect, the work of these societies will be to him an actual post-graduate school.

The past year has been one of the most important in medical affairs in the history of this association. The establishment of the Epileptic Colony at New Castle, in the first place, is a great philanthropic as well as professional advance. The commission in charge has wisely purchased a highly cultivated tract of land, although by doing so their appropriation was so drawn upon that but two buildings can be erected at present. However, this will enable the institution to begin its beneficent work with seventy-five inmates next autumn. As rapidly as possible the colony will be enlarged to accommodate 1,500 persons, now, unhappily, dwelling in jails and infirmaries.

Next, the Laboratory of Hygiene has started on its successful labors. This institution has a double function. For the general public it stands between them and impure and unwholesome food, and provides the possibility of pure water. For the profession it will secure reliable drugs, assist in obtaining an absolutely accurate diagnosis in suspected cases of fever or tuberculosis, and within a few hours furnish positive knowledge as to whether a given case is tonsillitis or diphtheria. In addition to these material advantages there accrues to those who are remote from institutions devoted to scientific medical work that feeling of satisfaction which results from the possession of the same laboratory advantages, which until now have been the privilege of city practitioners only. The stimulation to do better work must result in an added dignity to our ministrations, thus removed from dubiety and placed on the level of true scientific labor.

The prestige of medicine in Indiana has been greatly advanced by this acquisition. Since this association proposed, and by its corporate influence, as well as by the individual efforts of its members, has secured the enactment of most of the health laws of the State, and since this interest has continued and thereby assisted in the enforcement of these acts, it is proper that the achievement of public health work be reviewed. Complete mortality statistics have been collected over the entire State since 1899, and these are tabulated and scientifically analyzed. The excellence of these compilations has resulted in their being sought by libraries all over the Union, and by many foreign governments, and the future issues have been requested for all these institutions.

The people are constantly advised in sanitary matters, the authorities are aided by pertinent suggestions, school children are daily examined by simple methods, as to sore throat, eruptions, etc., and in many counties the sight and hearing of the pupils are now as carefully tested as is their mental status.

In 1905 Indiana's death rate decreased 0.3, as compared with that of the last six years, a net saving

in lives of over 700 per annum. In 1904 there were 4,948 deaths from tuberculosis in Indiana, and in 1905, 4,492 deaths, a decrease of 356, or nearly one life a day saved.

Although this question is to receive your attention in the symposium on tuberculosis, the opportunity to urge united and individual effort in securing the enactment by the next Legislature of a statute providing for a sanatorium for the treatment of tuberculosis cannot be passed; we must urge the commission appointed to investigate the question to report with a recommendation that this great work be at once instituted, and that a sum of not less than $150,000 be appropriated to inaugurate the work.

Typhoid fever killed 1,013 citizens in 1904, and 928 in 1905. None should have died, but hundreds escaped the disease through the tireless crusade of our members for purer water, purer food, and more sanitary homes.

A discouraging item appears, however, when it is shown that 178 mothers perished from puerperal infection last year, an increase of eight over the year before, but the large number of accouchements either unattended or, worse, attended by ignorant midwives, may clear us of some of this disgrace. Yet the dirty-fingered doctor still exists, and is most often met with in the city.

There is a grim significance in the mortality of cancer, which claimed 1,159 victims in 1904, and 1,425 in 1905, an increase of over 6 per cent. Fifty-three citizens in every 100,000 of our population died of cancer. While this disease has had longer and closer study than any other of the great assassins of humanity, it is apparently increasing in all parts of the world. I say apparently, for the conclusion is deduced from statistics, necessarily imperfect and without regard to the irregular increase of population. However, even though the returns are faulty, and not the proper basis for the support of a theory (for instance, that of contagion or heredity, or of the existence of a cancer parasite), more deaths are known to occur each year wherever records can be obtained. It is a familiar saying among pathologists that the discovery of the real cause of cancer, or that which is more vitally of interest, of some biological, or other method of curing it, is quite as likely to occur in a small, obscure laboratory as in the perfectly equipped pathological department of a great university.

But by far the most important event that has occurred in the State in the last year, with which the medical profession is concerned, is the union of all the medical colleges in the State, as the Medical Department of Purdue University. In discussing the progress of medical education, Dr. Osler (if I may be again permitted to quote from his great farewell address) said: "The urgent need is a consolidation of our medical schools. Not only in this city, but in Richmond, in Nashville, in Columbus, in Indianapolis, and in many other cities, a merger is needed. Even the larger schools of the larger cities could pool their scientific interests to the great advantage of the profession."

In briefly reviewing the world's medical progress in the past year, some noteworthy work is observed, and no subject in pathology has received closer attention than cancer. The opinion hopefully advanced a few years ago that cancer was certainly of parasitic origin has quite generally been reversed and is no longer entertained, except by a small minority of competent investigators. In the third report of the Carolyn Brewer Croft Cancer Commission of Harvard Medical School details of exhaustive experiments are presented and the conclusion in every instance fails to show the slightest evidence of simple parasitic infection. These experiments were made by pathologists of the highest skill and of unbiased minds, and their deductions are authoritative. The negative results obtained by the members of this commission have, to their minds, left the theory of Cohnheim unshaken. In a review of the year's work on cancer in the *Interstate Medical Journal* for January, 1906, Karl Fisch said: "The reports of the different cancer institutes and laboratories, except that of the New York Institute, are uniform in their conclusions. They have done a great deal to bury finally the parasitic theory based on the presence of cell inclusion." In a personal letter an eminent New York pathologist says: "So far as I have been able to learn, pathologists quite generally discredit the work of the Buffalo Laboratory." But the work of the Buffalo group of investigators, even if not accepted, has been very important. The question must be admitted to remain an open one.

In April, 1905, Drs. Schaudin and Hoffmann of Berlin published a report of work which they have done in reviewing the investigations of Dr. Siegel, also of Berlin, on protozoa he had found in luetic lesions. By the aid of very powerful microscopes they detected constantly another very minute organism in these lesions. This organism they called *Spirochæta pallida*. Following their announcement, in the past year over a hundred observers have confirmed the regular presence of this *Spirochæta* in the initial lesion, in buboes, in twelve or more hereditary luetic infants, and in the tissues of various internal organs. In Metchnikoff's experiments with lues in anthropoid apes the organism has been found in four out of six cases.

While at present the demonstration of *Spirochæta pallida* as the single cause of lues is not positively accepted, the constancy of its presence in a luetic during the contagious period of the disease, and its absence in a nonluetic have a significance that merits the most thoughtful attention and expectation that its causative relation may be ultimately proven.

Since the discovery that the malarial parasite was introduced into the blood through the sting of the anopheles mosquito, and that the bacillus of plague was disseminated by rats, the part played by insects and animals in spreading infectious disease has received careful study. The first very important result was that infection through the sting of the stegomyia was the sole cause of epidemics of yellow fever, and, what was of vastly greater benefit to humanity, that the destruction of their breeding places and larvae, and the exclusion of the mosquitos was an absolutely certain method of checking the disease. In the past year this line of investigation has shown that bed vermin, having bitten a person sick with pneumonia, will infect others by transferring the *Bacillus lanceolatus* through their bite. Also that the lanceolatus, having passed through the respiratory and alimentary systems of the common mouse, becomes vastly more destructive when reintroduced into the human organism. These are facts of practical importance, suggesting as they do the abatement of this form of infection through domiciliary cleanliness.

The most valuable contribution to parasitology in the past year was made by Robert Koch. In his "Preliminary Report of an Expedition to East Africa," published in November, 1905, and abstracted in the *Post-Graduate* for January, he gives the most minute account that has yet been written of three diseases intercommunicable between domestic animals and human beings—African recurrent fever.

Texas fever, and the sleeping sickness. His observations of the habits of the insect carriers whose bite disseminates these diseases have enabled him to suggest valuable expedients in avoiding these infections. Our own fellow-countrymen, Novy and Vaughan, had already made very valuable contributions to the study of the protozoal diseases. It is research work of this character that must ever command our highest professional respect. Animated by no other interest than a purely scientific one, a scholarly desire to know the cause of these diseases, and without any prospect of gainful advantage, these scientists have spent time and treasure for this end.

Time forbids even a brief consideration of the year's surgical progress. Conservatism is probably its dominant note, and the startling successes attained in nerve, brain, and blood-vessel operations indicate that surgery's next triumphs will be in this field.

The ceaseless demands of medical science require a diversity of effort that is infinite. None can shirk his part in the great plan. Some will achieve largely and reap rich harvests of temporal gain or eternal remembrance, but most of us will quietly do our work; our greatest fame the fealty of a few grateful hearts; our recompense a final peace at life's twilight hour. Yet each of us may profit in that larger sense which, recognizing worth in another, seeks honorably to emulate his efforts by producing better results in our own chosen labors; and while in our ethical relations we do well to affirm our abiding veneration for the oath and gentle admonitions of Hippocrates, let us take heart at the memory of the struggles that our patron of independent thought endured, with a mantle of charity for his faults and a grateful recognition of his lesson of personal research.

In his beautiful word-picture of the passing of Paracelsus, Browning says: "Meanwhile I had done well, tho' not all well. As yet men cannot do without contempt. 'Tis for them, good, and therefore fit awhile that they reject the weak, and scorn the false, rather than praise the strong and true in me. But after they will know me. I press God's lamp close to my breast. Its splendor soon or late will pierce the gloom. I shall emerge one day."

817 South A Street.

THE INSANE LOVERS.

By JOHN W. STEVENS, M.D.,

ASSISTANT PHYSICIAN LONG ISLAND HOME, AMITYVILLE, L. I.

The poets tell us that love blinds, and we all know that it makes fools of all lovers on occasion. Let any man who doubts this look back in his own experience for incontrovertible evidence of the truth of my statement, or, if he has not been so fortunate as to have been so affected, let him but spend a day in a Pullman car with a newly married couple. Thus it might be said that in this sense all of us might be included under the above caption, and that a certain degree of physical and mental aberration on this subject will be the *normal* experience of each of us. It is not with the normal, however, that I would deal here, but with the abnormal, those presenting a true mental disease, the prominent clinical feature of which is the existence of a love unfounded upon reality, unsought and unsuggested by its innocent victim, and having its only basis and origin in the disordered and diseased imaginings of the patient.

This subject is one of much importance to the general practitioner. Such cases are not uncommon in asylums and in neurological practice. The patient may seem so clear and rational on all subjects aside from this particular delusion that those with whom he is in daily contact may for a long while be deceived into believing him entirely sane. It is the general practitioner who will first see these cases, and hence it is very essential that he should have a clear conception of the condition, so that the patient's mental illness may be early discovered. When the patient is a young woman who coherently, with detail, and with seeming rationality, recites to her friends her story of disappointment and desertion, one may readily see what serious consequences might befall the innocent object of her delusion, if her mental disturbance were not recognized. No doubt many a suit for breach of promise of marriage is to be traced to the existence of such delusions in the plaintiff.

These cases do not in themselves constitute a separate clinical entity, but come from the ranks of the victims of three great mental diseases—paranoia, dementia præcox, and manic-depressive insanity, this insane love being but a prominent symptom. In paresis and senility, and possibly in some other deterioration processes, we sometimes meet with a condition approximating this in certain features, which I will touch upon in passing.

The Paranoid Class.—Here the love is a part of the systematized delusional state that goes to make up the clinical picture of paranoia. This psychosis is a disease of early adult life, usually making its appearance during the third decade, though in a small number of cases not before the involutional period. It develops upon a defective constitutional basis, congenital or acquired, as manifested through the presence of the stigmata of degeneracy, both psychical and physical. Probably no mental disease in its etiology depends more completely upon heredity. "So seldom, indeed, can the disease be traced to post-natal causes that the paranoiac may be said to be one predestined to his morbid peculiarities." (Berkley.) This does not mean, however, that a history of well-defined insanity must be found in the family. The various nervous diseases, alcoholism, criminality, prostitution, eccentricities, etc., in his antecedents, indicating the degeneracy of the stock from which he springs, endows him with a deficient and structurally weak nervous system. This is often shown in the peculiar mental makeup of such persons. From childhood they are often marked as strange and peculiar. At school they may be precocious in certain lines, but unequally so, and are apt to be deficient in the exact sciences. They are frequently shy and seclusive and fail to associate with other children. They may show a lack of affection, moral lapses, etc. As they grow older, there may be undue irritability with outbreaks of furious passion; others are suspicious, dreamy, mystical, or unduly pious. At puberty sexual perversions may appear. As they reach maturity and their sphere of activity and association enlarges, their earlier tendencies become more marked, and they are often flighty, unsettled, and unstable in business and their other undertakings. Their one-sided development may bring forth a genius in special lines of work with brilliant attainments. Associated with these mental deformities are many physical stigmata of degeneracy, such as facial and cranial asymmetry, illformed and unevenly placed ears, defects and abnormalities of the palate, asymmetrical limbs, etc.

The heredity and early history of these cases is very important to the clinician, often furnishing the first clue to the true mental condition of the individual. This abnormal love springs from some autocthonous psychic process in the patient, the pri-

mary origin of which must remain shrouded in mystery. The first expression of the psychosis, paranoia, is manifested in the patient's peculiar mental attitude toward the world, the misinterpretation of the simple events of everyday life, and a tendency to find in the most commonplace words and actions of others a hidden and occult reference to himself. Various abnormal somatic sensations accompany this mental change, for which the patient seeks an explanation, and then closely following, hallucinations of the various senses occur. A direct statement may be thus received from the "voices," finding the ready acceptance in the mind of the patient that we all give to impressions received through the medium of our senses. These hallucinations may first occur at night, and be half dreamy in character. So, in the presence of abnormal sensations in the region of the genitalia, there may arise delusions of sexual intercourse, with the subsequent evolution of a delusion of marriage. Be its origin what it may, there arises the fixed and unshakable belief in the existence of a love and understanding between himself and another, proof of which he finds in an unmistakable line of circumstances pointing thereto.

Though the details of the clinical picture may vary considerably in the different cases, the fundamental condition is the same in all, viz., a chronic progressive system of delusions in no essential points different from any other case of paranoia.

In the milder cases the patient may be so clear and rational on all topics aside from that of his delusion as to be able to maintain his relations with the world, and continue his regular occupation for a long time. His everyday associates may for a long while fail to recognize his delusions as such. In others this love is but one of a multitude of delusions. These patients, as are other paranoiacs, are coherent in thought, and able to converse quite well upon ordinary topics. When the realm of their delusions is entered, they become illogical in their reasoning and the conclusions which they reach, because of their erroneous premises based upon a misinterpretation of facts. Consciousness is clear, and orientation unimpaired, save in respect to person, when they not infrequently mistake the identity of individuals. Delusions of reference, wherein they misconstrue simple events as proof conclusive of their delusional beliefs, and retrospective falsification of memory whereby they find in their past life occurrences now having an altogether different meaning than they gave them at the time, are characteristic symptoms.

Not that there is any essential fundamental difference between them, but for the sake of easier description, the "lovers" may be divided into four classes:

First: Those in whom this love and the belief in a marriage to occur or already consummated, with the ideas going to confirm this belief, constitute the clinical picture.

Second: Those cases in which the delusions of love and marriage are associated with many others which upset entirely their relations with the world.

Third: Those in whom there are many delusions of grandeur and persecution, the patient attributing this persecution to the machinations of disappointed suitors.

Fourth: Those in whom there exists a distant, holy, and altruistic affection, without any active effort toward a material union with the loved one.

Such a division is really of little practical worth, since there is no sharp dividing line between the different classes, and as the years go by they all come to present practically the same clinical picture.

The First Class.—The general manner and behavior of these patients may be so little different from that of the normal fiancé as not to at first arouse any suspicion of the mental disorder present. It may be a nice medicolegal question to decide whether the patient's story of love and courtship is a delusion or the truth. There gradually arises in the mind of such an individual a belief that he is to be wedded to a certain person, whom he may know only slightly or has not met at all. This belief may find its origin in hallucinations, day-dreams, etc. He gradually comes to know that she loves him because of her peculiar expression and manner while in his presence. A chance word, look, or act reveals to him her feeling. He may at first be surprised, but looking back into the past, he sees many little things that he now understands in an entirely different way than he did at the time of their occurrence. She always seemed embarrassed while in his presence, flushed when he spoke to her; once in passing, she brushed against his hand, etc. Having been casually thrown in contact by their daily duties, he looks upon this as an intentional act upon her part that she might be near him. At one time she made some commonplace request of him, such as any woman might make of any man whom she has ever met, which he now sees indicated her affection for him. He now begins to watch her and finds that she wears her hair in a certain way, walks on a particular street at a given time where he meets her, and a hundred other little things in her daily life which really have no reference whatever to him, but which he interprets as clear proof of her love. He notices that her father is making certain changes in his business, which means that the father is preparing a place for him. Their residence is being repainted; a new house is being built in some part of the town, all in preparation for his approaching marriage. Evidence of the same thing may be found in chance words and phrases in the daily papers, which he believes she has caused to be inserted to indicate her love, what is being done in preparation for their marriage, etc. This latter is particularly apt to be the case if the loved one is a person of high degree whom he has never met. Not infrequently the published accounts of the approaching marriage of some prominent person brings forward one of these individuals. Just before Miss Roosevelt's marriage a man presented himself at the White House and declared that it was he, and not Mr. Longworth, that was to marry Miss Roosevelt. He explained that his mother was the Queen of Denmark and that she had arranged his engagement to Miss Roosevelt. The looks that the servants and passersby on the street give him, show that they know he is soon to be the husband of the daughter of the house, and she communicates with him by signs, such as the burning of a light in a window, or the drawing of a shade. Hallucinations may be present in such a case, and the patient hears people on the street talking of his love; he hears her voice, particularly at night, and she may appear to him. He may believe that she comes to his bed, and that he has intercourse with her. Others may mistake the identity of their lewd women associates, believing one of these to be his loved one who has sought this method to reach him. In due season he proceeds to prepare for the wedding, and notifies his friends of the approaching happy event. He buys the ring and gifts for her, and presents himself at her house for the ceremony. Up to this point his conduct may not have differed from that of the normal lover, save that it is based upon delusions. The belief arises in some that the ceremony has already been performed, and he simply prepares to take up

living with her in the usual way. He endeavors to reach her, and when deterred by her relatives, or refused by her, there arise delusions of a conspiracy to keep them apart. At first, and even for months, his attitude toward those who are, or he believes to be, keeping him from his loved one, may be one of mild but persistent protest, gradually becoming stronger, until he becomes quite determined in his demands. Finally, from exasperation, or at the behest of his hallucination, he may resort to violence or even homicide in his endeavor to reach her. It may be that the one upon whom he directs his attack has really had nothing whatever to do with his case. Whether actual violence is attempted or not, he sooner or later grows so annoying that his confinement becomes necessary. As the years go by his delusions multiply, his ideas of persecution or grandeur gradually evolving and extending in their scope.

In other instances of this first group, a woman develops an abnormal love for some man, frequently a favorite minister or priest. This may arise in the case of a young woman, or a spinster at the involutional period. Clouston described the latter under the caption of "Old Maid's Insanity." No man in the community is normally so much in the minds of all the women as is the dominie, and even the staid and settled old married woman has a great deal to say about her preacher. Next, and a close second, comes the family doctor, but any man of her acquaintance may be selected. I will take the case of the minister as the type. The patient is an individual of degenerate tendencies. From a lack of attractive qualities, perhaps, she fails to receive the same degree of attention from the men as do her more fortunate sisters, or from an inherent tendency to mysticism and piety she devotes much time to religious matters and church work, with a consequent close association with the priest or minister. At first, probably through her idealistic reverence for his holy office and high character, she lifts him to a pedestal of admiration in her mind, endowing him with all the qualities of goodness and virtue that she holds as her standard. This gradually evolves itself into a love of more or less pure and exalted type, which she may or may not in course of time come to believe that he reciprocates. In case of the latter belief, she finds evidence of this in his attentions and manner toward her, which are in reality of the most ordinary and disinterested nature. She then begins to try to show him in various ways her feeling toward him, writes affectionate letters, follows him about in the course of his duties, etc. Her attentions become embarrassing and annoying, at first probably occasion great surprise, are ignored, politely discouraged, and finally, in desperation, she is ordered to discontinue her undesired attentions. This is not effective, however, and she continues her manifestations of affection, gradually presenting evidence of the delusional basis of it all in her misinterpretations and misconstructions. She may at first be hurt and much cast down that her love is thus rejected, speak of her own unworthiness, and take to herself the blame for his neglect. The presence of delusions of reference is here brought out in the excuses she offers for herself and her attempts to secure his forgiveness for wrongs that she thinks he believes she has done him. Thus, two years afterward one young woman wrote begging to be forgiven for having refused to go on a sleigh-ride to which she had been casually invited along with a dozen others. She admitted that she did not go because she was "jealous," but of whom she did not state. Such delusional interpretations or hallucinations may exist for years before they so affect the patient's behavior as to make her mental disorder recognizable. Also, such a condition of mind may possibly exist for months, or even years, without active efforts on her part toward the attainment of the object of her love. Or, on the other hand, because of her belief, founded upon her delusions and misconstructions, that he knows and reciprocates her love, she quietly and systematically goes about the preparations for her marriage. Through the presence of sexual perversion, undue sexual excitement, or pathological sensations in the genitalia, half-dreamy sexual hallucinations may occur at night, from which there develops the delusion of sexual congress with her lover. Ultimately her delusions so increase in prominence and scope, and she becomes so troublesome that her confinement in an institution becomes necessary.

The following patient, an example of the first class, has given us a great deal of trouble for nearly two years:

H. S., female, white, age 32, single, formerly a nurse in the Long Island Home. Family history negative so far as I am able to ascertain. Facial asymmetry and badly formed features. In disposition reticent, seclusive, and exceedingly suspicious. Because of her peculiarities, she was discharged from the employ of the institution in May, 1904. It was subsequently discovered that she had, previous to her discharge, developed a line of delusions in reference to Dr. X., one of the assistants. Just before leaving, she purchased several hundred dollars' worth of clothing in anticipation of her marriage to him, though she did not state so at the time. Some weeks after leaving, she wrote the doctor asking for money, but did not give any explanation for making such a request of him. Her letter being ignored, she wrote again in a few days, addressing him as "My dear husband," and signing herself "your loving wife." Dr. X. at once wrote to her sister, telling her that H. S. was insane, and inclosing to her the letter he had just received. The family took no action in the matter. A month later H. S. returned to the Home and asked to see Dr. X. When told that she could not see him, she threatened suicide, and was at once taken into custody by the officers of the Home. Several articles of jewelry with the doctor's name engraved thereon were found in her possession. Upon her brother's arrival in response to our message, he told us that his sister had left home with the statement that she was going to Amityville to be married to Dr. X. He and the rest of her family and friends believed her story to be true. She had told him that an addition to the female department, in course of construction when she left, was being built for her and Dr. X. to live in. Even after being shown the completed structure, which it would be absurd to believe had been built for any such purpose as she stated, he was still unconvinced that she was mistaken. Though he removed her as we directed, yet he left with the feeling that his sister had been wronged and deceived by Dr. X. Since that time the patient has continued to deluge Dr. Wilsey and Dr. X. with appeals for assistance in securing work, in spite of the fact that she has been told time and again not to communicate with us further, and that we would have nothing to do with her. After the one instance, she always signed her letters with her right name, and until recently she did not directly mention her love for Dr. X., nor the relations she believes to exist between herself and him. When about to leave the employ of the institution, she did not go on the date set for her leaving. She told Dr. X. that she could

not go until she received a remittance from her brother, she having spent all of her own money, and asked Dr. X. to allow her to stay until she did hear from her brother, which request he naturally granted. She afterward laid great stress upon this as an evidence of the doctor's love for her. In reality, there was never the slightest foundation in fact for her belief that Dr. X. cared for her. He never paid the slightest attention to her, and it is doubtful if he ever spoke a dozen words to her except in relation to her work. Since she left the institution, she has spent part of her time with her sister, but for a year or more past has been employed as a domestic. In the community in which she lives she is looked upon as a normal individual, and I believe her family consider her as such. Seemingly of late her delusions have become more active, if such a term is permissible, and I cannot better indicate her present condition than by giving copies of her last three letters. The incident of the sleigh-ride of which she speaks was really very unimportant. As I recall it, a party of a dozen patients and nurses was being made up, and she was simply told that she might go if she wished.

O——, N. Y., Jan. 26, ('06).

Dr. X.: I am going to do a daring thing. I am going to ask you to send me some money. perhaps you will say I am crazy that "I spent my money all on your account" and "I imagine you knew I was" and why dident you tell me I was foolish to do so. But I don't suppose you realize what that money was to me, as you have everything in plenty. I hope you always will. The name you have given me, I suppose my word is void, but there are a few that think me the same as of old, my minister for one. Only hoping you will look at this in the same light as I do. If you do think me crazy, don't for pity sake tell it to the whole world again, of course I don't think I am crazy, but I do think I have been most ungirlishly foolish. hoping you will have a little mercy, I close hoping to hear very soon.

Yours truly, H. S.

In a postscript she gives some details of her daily life.

The following was written under date of February 5, 1906:

Dr. X.: I feel as though I must tell you all tell you that I love you, and that if you was only mine I think I would be the happiest girl in the world.

Dr. X., will you not forgive me for not going on the sleigh-ride that night. I was a little jealous and it was very rude of me not to go, and had I thought how discourteous it was to you, and perhaps to Dr. Wilsey, I would not have done it for the whole world. Won't you please forgive me? I worshiped you Dr. X. when I was sick in bed down there, if you knew how much good it done me, only to hear your voice, and how I longed to put my arms around your neck, and tell you that you was dearer than anything else in the world to me. Dr. X. if you only care for me, I will go any place, or grant any wish which you may ask, that lies in my power. I will say good night, hoping you will write me soon as you receive this, I remain sincerely yours.

H. S.

O——, Feb. 10, 1906.

Dr. Wilsey: You have told me again for the 175th time I guess, not to write to you again, but will you not forgive me for writing? and will you not forgive me for not going on the sleigh ride, truly I never thought how rude I was acting. Please forgive me for everything I did that was wrong. Dr. Wilsey havent I done as you wished when I told Dr. X. I loved him? I imagined I had, am I right. I wish I had told him before I left, so I would have known whether or not he cared for me, one reason I did not tell him, I was afraid he might take it as an imposition.

Now if I have done as you wish Dr. Wilsey, you will help me will you not. Let me come back or something. I see no pleasure in life in doing housework outside of your own home, but I sometimes think now, I might be obliged to, or work out all my life. Wont you please write and tell me Dr. Wilsey. I am so anxious to know. If you could only realize my trouble.

"Without a home," the reason all this is such great trouble to me.

I cease with good night only hoping to get just one line of good news. If it cannot be, I want to know the worst, as it is very important to me.

from H. S.

The Second Class.—In this group the love is associated with a mass of delusions involving all the individual's relations with the world. Ideas of grandeur are often a prominent feature. It seems more probable that here the delusion of love and marriage is a secondary one, arising as a part of the systematization of other primary morbid ideas. These patients, like those of the other class, are individuals of degenerate tendencies, are different from their kind, often shy, timid, and seclusive, and not infrequently there exist sexual perversion, habits of onanism, etc.

The psychosis once established, there rapidly appears the common symptom, hallucinosis of the various senses, with a special prominence of abnormal sensations in the genitalia. From these arise delusions of sexual intercourse. God, Christ, or the Holy Ghost nightly come to her arms, or, instead of such supernatural lovers, her prince, knight, or it may be but an ordinary individual of her acquaintance, lies with her. From this point it is an easy feat for the diseased mind to pass on to the belief in a supernaturally performed marriage. With her illogical reasoning, misinterpretation of the commonplace events in the lives of those about her, her delusions of reference, retrospective falsifications of memory, and hallucinations, she builds up a coherent system and explanation for her delusions. She looks back into her past life and reads into its events a system of evidence showing that from the first she was predestined to a high and honorable marriage. In fact, that she herself springs from high and noble lineage, and on some delusional premise, explains the fact that her early life was spent amidst adverse circumstances and poverty. Those with whom she has lived are not really her parents, but she is the daughter of some wealthy and high-born person; was stolen by her foster parents as a part of a conspiracy to deprive her of her deserts, or that she might pass through this probationary period of reverses in order that she may the more brightly shine when she finally does come into her own. Proof of all this is received through the medium of hallucinations, or in the misinterpretations of simple events of the past and present. Now that she has discovered her true position, she may calmly and quietly await the coming of her lover or husband, knowing that all will come out satisfactorily in due time, or, as is more often the case, she attempts to establish communication with him, writes many letters to him, and finally tries to reach him in person. It is at this point that these patients become particularly dan-

gerous. The rebuffs from the man himself, his denial of all connection with her and refusal to see her, are due to the machinations of her enemies, who have control of him, as are the attempts of his or her friends and relatives to keep her from him. She finally sees that she will be able to accomplish her desires only by violence, and, fixing upon a particular individual as the instigator of her troubles, a tragedy follows. Should she thus resort to violence, little or no effort is made to escape detection, since all the world will now see to what persecution she has been subjected, and realize that she has taken the proper course. Her actions may be dictated and governed entirely by hallucinations, the "voices" telling her what to do.

Such are the individuals, male and female, who follow about from place to place and annoy men and women in public office or prominent position. Usually the object of this love is in a relatively much higher social position.

The Third Class.—These patients, along with their delusions of persecution and grandeur, assume a different attitude toward their supposed lovers. The majority of this class, I think, are women.

Because of her great wealth or unusual beauty and accomplishments, many men of more or less importance seek her hand in marriage, and in their disappointment at her refusal of their offers, do all sorts of things to annoy and persecute her, and even attempt her life.

Such is the condition present in a patient now under my observation. Many men of prominence have sought her hand because of her great wealth, but she has spurned them all. In their disappointment they have combined, and seek to destroy her. The officers and nurses of the institution are their agents. They annoyed her for years in her own home, and finally caused her to be sent here. She is constantly spied upon, her food contains poison, and the most disgusting filth; electricity is used upon her, foul odors are blown into her room, carbolic acid put into her drinking water, etc., all at the instigation of these men. These delusions are well systematized. Hallucinations of hearing, taste, and touch are present.

Some years ago there was brought to the Home a young man presenting a line of symptoms corresponding to those of both the first and third group of lovers. He fell in love with a young woman who worked in the office opposite his. He had never been formally introduced to her, and his acquaintance with her was limited to one or two casual meetings in the corridors of the building and on the elevated train. He spoke to her and had some little conversation with her on one occasion, but she maintained that she neither said nor did anything that would justify his after-conduct. He believed that she was in love with him, in spite of her statements to the contrary, and on two or three occasions he went to her father's house and demanded her hand in marriage. He became so excited and threatening when his demands were refused that it was necessary to drive him from the house. He grew very despondent in his disappointment, abruptly gave up a very profitable business, and announced his intention to go to another city and begin life over again. He now began to imagine that the people on the street made insulting remarks about him as he passed. This was particularly true of young women, and often the girl would turn to her companion and say, "I would marry him," referring to the patient. This annoyed him greatly, and he wandered from town to town, but the same condition met him everywhere. He actually feared that he would be married against his will and efforts. He believed that everyone knew of his love affair. He showed no mental disorder aside from this, and while at the institution, behaved in a very pleasant and gentlemanly way at all times.

As a fourth class I will mention those cases described by authors as having sexual hallucinations and maintaining a holy and distant love for the object of their affection without ever openly announcing to him its existence, or seeking for its material consummation.

In the recognition of the paranoid lover a study of the individual's heredity and early history is important, the discovery of a defective heredity and of physical and psychic stigmata of degeneracy being of value as presumptive evidence. In many cases the presence of frankly expressed and easily discernible delusions of persecution and grandeur, hallucinations, etc., or the exalted position of the loved one renders such a claim so absurd and impossible as to make the true nature of this pathological love readily apparent. As we all know, the paranoiac is always capable of more or less logical reasoning on any point off the subject of his delusions, and as is limited the scope of his delusional beliefs, so will it be increasingly difficult to entrap him into a palpably insane statement. Along certain lines he may be capable of even brilliant intellectual work. As a matter of fact, he is more or less influenced by his delusions in everything he thinks and does, but he is often able to conceal this from others for a long time. Also quite a degree of cunning is a very marked characteristic of the paranoiac, he at times being even more adept in simulation and deception than a normal individual.

At the present time I have under my care a young man, a paranoiac, who for eight years past has spent most of his time in institutions. Yet after coming to us a year or so ago, he so cleverly covered up his delusional ideas that it was two or three months before we were able to elicit from him any expression of them. During this period he was allowed many privileges, and was in constant association with normal individuals, where he comported himself in as irreproachable a way as they did. There came a day when the mask was dropped, and he revealed a wealth of delusions impossible to enumerate, ramifying into and involving every act of his daily life. They, too, are of the most fantastic and grandiose type—he is ordained of God to reform the world, all present forms of government are wrong and he is going to right them, he knows more about political matters than anyone else in the world, but he has been hounded and persecuted by the Jews for years, and prevented from putting his ideas into effect. Many attempts have been made upon his life, and he is constantly in mortal fear. Every act of his daily life, and of those about him, has some reference to and bearing upon his case. Yet two days after telling me these things, at a judicial inquest to determine as to his sanity, not one delusional admission could I wring from him, though I faced him with his own words. He either denied the statements implied to him, or adroitly explained them away.

If such difficulty is to be met with in a case possessing hundreds of delusions, then we may readily understand how difficult it often is to settle the question of the sanity of some of the less effulgent types.

In the "milder" cases of the lovers we must consider the relative positions of the two individuals, and take cognizance of the degree of probability that might be attached to their claims. There may be a manifest improbability or impossibility of such a

union occurring. It may be found that the two have never even spoken to each other, or that the lover is totally unknown to the loved one.

Having established the real existence of facts upon which he bases his claims, then must be determined the rationality of such deductions. Search should be made for hallucinations of the various senses, delusions along other lines, and retrospective falsifications of memory.

The fact that despite every effort on the part of the loved one to discourage her advances and to show how distasteful to him are her attentions, she does not desist permanently, as a normal person ordinarily would, is a point of importance, particularly in women.

Dementia Præcox.—We find an occasional example of the lovers here. In the paranoid type of the disease cases may be met resembling in a superficial way the true paranoiac lover. We have usually a degenerate basis. A delusion arises that he is to wed, or is already wedded to an heiress, popular actress, or other woman, and hallucinations, which are usually very active, confirm his belief and direct his conduct. He may seek to reach his loved one. Restrained from doing so, he manifests no strong feeling either of disappointment or resentment. He makes no special resistance when detained, and in an indifferent sort of way, details his delusions. These will be found to be of a silly and absurd character, and with little or no system. Hallucinations are usually a prominent symptom. After being sent to an institution he may retain his delusions for some months or years. He makes little effort to act upon them, may express them only as a result of questioning, and fails to show any strong feeling about the matter. This emotional deterioration is a prominent feature, and is manifested in other lines, as his lack of interest in anything, indifference toward his family, his own future, etc. In the course of time, as a rule within two or three years, he settles down into a condition of dementia, with possibly a few residuals of his former delusion. Patients of the hebephrenic type, in the presence of deterioration and increased sexual desire, may seek promiscuous intercourse among their acquaintances.

This latter statement is often true of the paretic, who may be led to form many liasons. Occasionally he limits his attentions to one or two women, but more often this is not true, and his illicit relations are multitudinous if the opportunities present themselves. These patients are absolutely unable to realize that there is anything wrong in such conduct, but on the contrary often feel proud of the fact, and make no effort to conceal it from their wives or husbands. Such behavior, of course, arises as a result of deterioration, which, with his elation, expansive delusions, and the physical signs of the disease, make the diagnosis easy.

The childishness and weakened judgment of the senile frequently leads him into inadvised courtship and marriage. Frequently we see these old men enmeshed by some scheming woman whose only aim is to fleece him of his property, which he, in his weakness, is unable to realize.

Where deterioration is further advanced and the ethical sensibilities blunted, we find him forming disgraceful liasons. Some years ago such a case was aired in court. Improper relations arose between an old white man of eighty odd and a negro woman, who got more than half a million dollars from him. While the courts did not restore his property to him, holding that he had given it to her willingly while in a responsible mental state, yet we are forced to believe that there must have been considerable deterioration present to have led him to thus give away his property to such a woman instead of to his children.

The next group of cases to be considered are those found among the victims of manic depressive insanity, during the manic phase of that disease. Here the love is rarely a true delusional condition as it is in the paranoid states, and is present only during the existence of the manic symptoms, disappearing in the normal intervals. It finds its origin in the eroticism, the patient's tendency to tumultuous overresponsiveness to stimuli, and the lack of restraining ethical sensibilities in the presence of the elation and self-approbation characteristic of this disease. The tendency of the manic patient in all things is to an immediate response to his every impulse, and the restraining influence of a calm judgment is lacking. This is manifested in his many whims and vagaries, foolish pranks and doings, restless activity and multitude of new schemes, unstable emotional attitude, and over-susceptibility to suggestion.

The conditions exist alike in both male and female patients, though really it does seem that abnormal sexual excitement is of more frequent occurrence in women than in men. Of course the difference in the standards for behavior of men and women make lapses more noticeable in the latter. Still, it is a rare thing to see a maniacal woman in whom eroticism is not a very noticeable symptom, which certainly cannot be said of all maniacal men. Even though we grant that it is present in equal intensity in both sexes, yet we must admit that its manifestations are much more noticeable in the female, and also that, for obvious reasons, it is a more serious matter. Because of this lesser prominence in the male, and because of his greater opportunities to gratify the passions that do arise, I think it is doubtful whether we find very marked examples of the "lovers" among men suffering from this disease. A condition of excessive sexual desire, which if present in a woman, would send her to an institution, might be entirely overlooked in a man. Probably another reason why we do not notice sexual excitement so much in the maniacal man after he has reached a condition necessitating his being sent to an institution, is the fact that he there seldom comes in contact with members of the opposite sex. This is not true of the woman, for ordinarily her physician is a man, and it is generally he with whom she falls in love.

Upon this basis of changed mental condition and eroticism, the woman forms a sudden infatuation for the first man who shows her a little attention, or in whom she thinks she sees an attractive quality. This leads her into saying and doing things that in her normal mental condition she would not do for her very life. The degree of intensity of her mental disturbances determines the extent to which she oversteps the bounds of propriety.

Thus in the milder hypomaniacal cases, she manifests her feelings in a rather exaggerated phase of the little wiles and coquetries of her sex. She seeks every opportunity to be in his company, blushing, sighing, and simpering the while, shows her jealousy of his every attention to other women, makes him presents of flowers, candy, jewelry, etc., calls upon him to perform all sorts of little trumped-up duties for her, writes him sentimental letters, and does a thousand other little things that go to show a woman's love for a man. The erotic element present is shown by her insinuating and suggestive remarks and actions, and her tendency to the unnecessary exposure of her person.

As the degree of excitement increases, the conduct

of this woman ranges through all grades from that condition in which she openly tells him of her love, publicly embraces and fondles him, and seeks to keep him with her constantly, to that in which she openly and in the presence of others exposes and offers herself for intercourse.

In the milder hypomaniacal cases her love may be directed toward a single individual, but as her mental disturbance increases, so does her sexual excitement, with a consequent offering of herself to every man she sees. Even the hypomaniacal patient, though, is not absolutely constant in her love, and it is the man of the moment in whom she is the most deeply interested. Still, after all, and in spite of her many flirtations with other men, there is nearly always one particular individual for whom she has a preference.

This abnormal sexual excitement may be the first and almost the only evidence of mental disease in certain cases, and not infrequently it is this symptom alone that necessitates the young woman's confinement in an institution. Often she has a quite clear insight into her own condition, and recognizes the abnormality of her behavior, but is unable to control herself. Masturbation is not infrequent.

I will briefly outline below three such cases:

Miss K., æt. 24, at puberty manifested excessive sexual excitement, which was about the only recognized symptom of mental disorder. This subsided in a few months, only to reappear six months later. This time she was a bit restless, emotional, and slept badly. She was cared for at home during three or four such periods, but when at the age of 18 the same condition reappeared, her parents questioned their ability to protect her, and sent her to the Home. Since then she has been admitted five times, each time remaining three or four months. In the intervals she has had several periods of mild depression. Each time that she has been here she has presented practically the same condition. She is mildly elated and rather unstable emotionally. There is some increase of motor activity as manifested by her busyness in many directions. There is practically no disturbance of thought, she is perfectly clear and rational on all points, so that as far as her limited education will permit, she is able to make herself quite entertaining in company. As an evidence of how controlled she is, I will state that she usually makes the journey of several hundred miles to and from the institution unaccompanied.

Yet, as she fully realizes herself, recognizing its pathological nature, she is in a very erotic state at the time. During her last three trips to us she has each time lavished her affections upon the same man, one of the physicians. Her advances are, of course, firmly repelled, yet she makes the doctor's life a burden while she is here. She follows him about the halls and parlors, seeking every opportunity to be near him, and when this is not possible she takes her stand where she can see him, and would remain there for hours at a time, gazing at him in the most lovelorn manner. She is exceedingly jealous of any attention shown by him to any other woman in the course of his duties, this jealousy often sending her to bed in a storm of tears. She frankly admits her feeling for him and likes to make insinuating remarks about their marriage. In his presence, regardless of others, she tries to take his hand, to lean against him, etc. When reproved for her conduct she weeps and admits that she should not act so, but says that she cannot control herself. She begs us not to believe that she is always so. In the presence of other men, if the opportunity presents itself, she is prone to be insinuating in her words and behavior, but after all, she is completely the doctor's own.

She masturbates somewhat during these periods. In the intervals between these attacks, so her parents tell me, she is a very proper and reserved young woman.

Miss H., æt. 30. She springs from a markedly degenerate and neurotic family, both her father and mother having frequent periodic attacks of depression. The mother is of such an abnormally jealous disposition that she cannot tolerate her husband's attention to their own daughters. Miss H. has for ten years past had regularly recurring attacks of mild depression, alternating with a state of hypomania, which has once or twice passed on to a marked maniacal condition. These periods last two or three months, and are usually separated by a somewhat longer period of normal mentality. In the states of elation, eroticism is the predominating feature, and were it not for this she could be easily cared for at home. She is naturally a very refined young woman, and these qualities continue to influence her in her illness. Thus, while each time she usually selects some man to fall in love with, yet she is generally very ladylike about it. The very serious feature of her case is that during this excitement she makes all sorts of charges of improper conduct on the part of her supposed lover. She tells this in such a straightforward way, with such attention to details, and is seemingly so clear and rational, that on more than one occasion she has come near causing serious trouble for some innocent man. She always tells these stories very frankly to her father, simply as a report of happenings, often not seeming to feel it necessary to excuse herself at all. She once told her father, in minute detail, about how she started down a back stairway with a man, and that they had intercourse together there. On another occasion she came to the Home simply on a visit, and not as a patient. One of the physicians, Dr. M., in the course of ordinary civility toward her as a guest, showed her some little attention. The next morning she claimed that the doctor had gone to her room during the night and sought admittance. At first she said that she had received him, but later denied this. She remained a day or two longer, and then went back home. On the way she stopped and purchased a ring. When she reached home she showed this ring to her father, and gave him a detailed account of her marriage to Dr. M., and said that they had spent the previous night together in a hotel in New York. There was no question of the falsity of her story from start to finish, but she stuck to it for some weeks, when she finally admitted that she had concocted the whole thing. This, however, not until Dr. M. had suffered considerable embarrassment.

The third patient, Mrs. M., though the mother of three children, and in her normal periods a loving and dutiful wife, is yet ready at the onset of her manic period to desert her husband for the other man of her choice. It has been the same man, a physician, each time for the last five or six years, during which she has passed through three or four attacks. She recognizes her feeling for the doctor as abnormal, but says she cannot control it. She seeks his company, writes long letters to him, telling him of her love, and goes still further in her confessions as her excitement increases. Much of the time her excitement does not progress beyond the hypomaniacal stage, and aside from eroticism, and an increased motor activity as manifested in her exceeding busyness and multiplicity of new schemes, she shows little evidence of mental disorder. Once

the doctor reproved her for her actions and her improper feeling toward him, telling her that when she recovered she would regret her conduct. "Why," she retorted, "should I regret what I may have done in my mental illness any more than I should regret having had a rapid pulse during a fever?" It is a most remarkable thing that these three women, particularly the first and second, should have escaped thus far with their virtue intact, as they have, so far as we have reason to believe.

In certain prominent features the maniacal insane lovers differ from those of the paranoid class. In the maniacal case the origin of this love is always to be traced to the abnormal sexual excitement, increased susceptibility to stimuli, facilitated release of impulses, and the lack of the restraining influence of the ethical sensibilities in the presence of the elation and sense of well-being.

Delusions and hallucinations are nearly always absent at the inception of this love, and if arising later are but concomitant symptoms of the condition already established. On the other hand, in the paranoid case this love is but a part and parcel of a fixed, progressive, and systematized delusional state, frequently originated and fostered by hallucinosis. A strongly erotic element is not necessarily present. Further, the maniacal patient often recognizes the abnormal nature of her impulses, which is never true of the paranoiac. The paranoiac is practically always monogamous so far as personal inclinations go, the maniac often polygamous. In mania the love disappears with the subsidence of the active symptoms of the individual attack, while in paranoia it remains through life.

Since beginning the preparation of this paper a very interesting case has arisen here at the Home.

Mrs. Z., aged 42, was admitted to the Home in 1893, remaining with us since then. On admission she gave a history of alcoholic neuritis of eighteen months' duration, mental disturbance having been presented during the twelve months preceding her admission. The records indicate very active hallucinosis, and frequent outbreaks of boisterous excitement during the first two or three years of her residence here. There gradually supervened a condition of mild deterioration, as shown mainly in a defective judgment and a loss of energy or ambition to change her mode of life. For the past five or six years, aside from this deterioration, she has shown little mental abnormality; so little, in fact, that we have always accepted without question her statements about happenings of which she had knowledge. We have used her as a sort of watch dog to report any irregularity that might occur.

She has been a regular member of the choir and orchestra for years. One of the medical officers was greatly amazed when he received the following letter from her recently:

"You don't know a good thing when you see it. I bet I can knock out in one round *all* your New York friends, in that line spoken of. Not that I want to brag, but experience is the best teacher, and that was the unanimous verdict formerly. I wish often I was as free as I was then. Guess you know why; if you don't, you must be stupid, and that I know you are not, although such a performance as that the other evening with S. and M. (referring to the night nurse and another patient) hanging around would argue that. I or anyone else could give you cards and spades on it. If you only knew how ardently I desired that spoken of, you would lose no time whatever in making permanent arrangements suitable all around. That is, if you are not altogether *non est*, as your looks indicated. But I can rejuvenate all the same. I have done it before. Now don't be a fool, and let's hear of the grand change lively.

"Hotly,

"Yours—

"Etc.

"Don't think I am going to deluge you with notes. This is my last."

When questioned by the doctor as to what she meant, she was greatly surprised that he did not understand, and became much embarrassed. He elicited from her that she believed that on the night previous he had come to her where she was sleeping in the dormitory, with eight or ten other patients, and had made improper proposals to her. She related in detail the whole conversation she believed to have occurred, with all the associated incidents thereto. She gave the hour of his supposed visit, mentioned the door through which he entered, the names of the other persons present, just where he stood, what he said, did, etc., and altogether demonstrated the existence of a false memory picture as clear and vivid in her mind as could be the impressions left in the mind of a normal individual by an actual occurrence.

It was, of course, impossible to convince her that he had not been there as she believed. When he denied it, she begged that he would never mention the matter again.

I have puzzled over this a great deal, trying to determine whether this belief had its origin in a dream or hallucinations. I am inclined to attribute it to the former. Her letter is very suggestive of what her past life probably was, though we know nothing positively about it.

This woman has for years been in such a mental state that, were it not for the fact that she has money for her support here where she wishes to remain, she would be out in the world, where I have no doubt she would be received as a normal individual. Imagine what might follow her charges under the latter circumstances!

Finally, in closing the consideration of these cases, I am forcibly impressed by two thoughts:

First, of the consequences that might befall these female patients of the maniacal class, if unsurrounded by due precautions and protection. Second, of the injustice that might be, and doubtless often has been, meted out to both men and women as the result of charges laid against them by these patients.

MEDICAL INSPECTION IN PUBLIC SCHOOLS.*

By INEZ C. PHILBRICK, A.M., M.D.,

LINCOLN, NEBRASKA

WHAT the eighteenth century established for man, and the nineteenth for woman, the twentieth will establish for the child—the principle of liberty; in case of the child, freedom from handicaps of birth, from unhygienic and immoral environment, from the degrading tendencies of industrial enslavement.

In the light of to-day's philanthropic agitation and effort, the present trend of legislative enactment, we may confidently predict that this century will direct its chief effort and realize its most vital accomplishment in the interests of the child. The State is more and more assuming paternal supervision of the child; witness child labor and compulsory education laws,

*Delivered before the Nebraska State Medical Society, at its annual meeting held in Lincoln, May 3, 1906.

the juvenile court with coercive power over the parent, and laws requiring medical inspection of all pupils in public schools.

Of movements for the betterment of child life, none takes precedence of that which is the subject of this paper—medical inspection in the public schools. Medical and lay literature attest public interest in this movement, as does also the considerable recognition in practice it has received. Indeed, so considerable has the literature of the subject already become, that all possible to each succeeding writer upon it is reiteration (which the subject will abundantly bear), and the addition of each writer's mite of result.

As indicative of the trend of medical and lay thought upon this question, let me instance the resolution adopted by the American Medical Association at New Orleans in 1903, urging boards of health, boards of education, and school authorities to adopt measures looking to the examination of the eyes and ears of all school children. This resolution was later adopted by the Mississippi Valley Medical Association and by twenty-one State societies, Nebraska being of the number, by the American Public Health Association, and by the State boards of health of twenty States, and by the State boards of education of eight States.

A committee appointed by the American Medical Association at New Orleans to look into the matter of public school inspection reported in the *Journal* of the association, April 15, 1905, urging complete and systematic examination of schools and school children. This committee has been continued at the subsequent meetings, the General Secretary informs me, but no further action has been taken by the association. At a conference this year in London, Eng., of 170 delegates from various educational and medical societies, preliminary to the International Congress of School Hygiene to be held in London in 1907, a resolution was adopted that medical inspection of pupils should be instituted in all public schools, and that women, as well as men, should be made inspectors.

The urgent need of medical inspection of public schools is attested by the results of work done here and abroad during the last decade. In Edinburgh, in 1903, a medical census of the public schools showed 70 per cent. of the children actually diseased. Thirty-six medical inspectors, appointed in Berlin in the spring of 1904, report that out of 15,000 examined, 25 per cent. were suffering from general physical debility, 5 per cent. were tuberculous, 10 per cent. were undeveloped mentally, 15 per cent. were suffering from anemia, rickets, scrofula, etc.

Dr. Armand Levy, in Paris, in 1904, examined 710 children from 4 to 13 years of age, and found 29.6 per cent. suffering from disease of the rhinopharynx. Dr. Lewis Somers, in his exhaustive essay, Medical Inspection in the Public Schools, published in the *Medical News* of January 17 and 24, 1903, gives an epitome of the collective results of an examination of 104,629 school children by several European investigators. Eliminating acute and accidental illness and myopia, the morbidity varied from 20 to 61.7 per cent. (the latter percentage in girls in Stockholm). Dr. John Cronin, chief of the Division of School Inspection, New York City, reported in May, 1905, that under the new system of inspection instituted in March, 1905, from March 27 to April 28, 1905, out of 7,166 school children examined, 33 1-3 per cent. had defects interfering with proper study. In the latest report of Health Commissioner Darlington on Inspection in the New York schools, he states that during the year there were 55,332 children examined, and 18,844 were excluded from school for contagious disease. Of those excluded, 8,833 were for disease of the eyes, 4,692 for pediculosis, 2,018 for disease of skin, 312 for measles, and 74 for diphtheria. Sixteen thousand, three hundred and ninety-four or 29.6 per cent., had defective vision, and 18,182 had defective teeth.

In the Report of the Bureau of Health of Philadelphia for 1904, we find that the number of pupils excluded from the schools was 11,317. Of the exclusions, 737 were for acute infectious disease, or contact therewith; 6,690 for parasitic skin disease; 117 for other disease of skin. There were found 1,756 cases of disease of the eye outside refractive errors, and of the latter there were 6,438. There were 1,012 cases of disease of nose and throat, and 80 of disease of middle ear. Four cases of tuberculosis, 2 of epilepsy, and 18 of chorea are tabulated, beside infected wounds, fractures, etc. Three hundred and twenty-eight unvaccinated children were found in the schools. Recently the Child-Study Department of the Board of Education of Chicago found, on examining the eyes of all public school children in the city, 32 per cent. of boys and 37 per cent. of girls had defects of vision, falling two-thirds below normal. In Cleveland, Ohio, examination of 32,939 pupils showed 18.7 per cent. having defects of vision. In Minneapolis, 32 per cent. of 25,000 pupils showed defective vision. The investigations of six observers in eastern cities (quoted by Somers) showed impaired hearing in 20.33 per cent. of children examined.

Medical inspection, if it meet the two-fold need of pupil and public, must include supervision of the sanitation of the schools, and systematic, complete and frequent examination of the pupils. The requirements of efficient inspection are well set forth in the Rules of the Bureau of Public Health of Philadelphia, 1904, from which I quote. Under the head of Sanitation must be considered questions of overcrowding, heating, ventilation, illumination, cleanliness, water-supply, toilets, cloak rooms, cellars, and playgrounds. Inspection of the child should include detection of defects of vision—myopia hypermetropia, strabismus, astigmatism; defects of hearing, by watch and rule, with inspection of external ear; ophthalmic disease—conjunctivitis, trachoma, obstruction of lacrymal canal; diseases of throat and nose—tonsilitis, diphtheria, adenoids; disease of skin; of thorax; malnutrition; parasitic diseases. In New York, to these requirements are added inspection of teeth, and bacteriological tests of all suspicious deposits in the throat.

Various systems of medical inspection are to-day in operation. There may be required the complete examination of every pupil at stated intervals; or the medical inspector may be subject to call by the principal of the school, examining fully all children brought before him—the emergency system, so-called. There may be required examination of the eyes and ears of every pupil by the physician or by the teacher, the latter obtaining under the Allport system. Inspectors may give their services (the voluntary system) or be paid. Under any system, to obtain effective service, there must be organization of forces under efficient direction from within and from without. Chief inspectors should be sanitarians, chosen solely because of their interest in public health problems and their willingness to devote time and labor to the work. There should be frequent meetings of medical inspectors for the discussion of public health questions and for helpful exchange of opinion. Societies of Medical Inspectors have been founded in Philadelphia, Boston, and New York. The system of public school inspection should be subordinate to the State Board of Health,

or the municipal Board of Health, where one exists, worthy the name.

From the above enumeration of the requirements of efficient inspection, it clearly appears that the complete physical examination of the child can be made only by the physician; and that such examination must be systematic and individual. The emergency system is open to the objection that a large percentage of physical disabilities will inevitably escape the observation of the lay principal. Besides lack of medical knowledge sufficient to make the principal a competent observer, there will often be lack of interest, and possibly occasionally real hostility to the work. Medical inspection, if it be satisfactorily performed, must be remunerated. No competent physician can be expected to relinquish so large a share of time and income as his duties as inspector, if conscientiously performed, would necessitate. Voluntary inspection proved a failure in Philadelphia, where it was instituted in 1898, with 200 inspectors. Somers reported in 1902 that only about 10 per cent. of the original inspectors remained on duty, and medical inspection in Philadelphia had lapsed into a state of masterly inactivity. Now Philadelphia has 48 medical inspectors, paid $1,200 a year; Boston, 50 inspectors, paid $200 yearly; Chicago, 12 inspectors, paid $50 a month each; New York 53 inspectors at $1,200 a year. Chicago alone of these cities has the emergency system. Of special features of medical inspection which obtain in certain cities may especially be commended the psychologic tests made in the Chicago schools; the special classes for mental defectives, in Boston, and the nursing corps in New York. Health Commissioner Darlington, in his latest report, highly commends the work of the nursing corps at present in Manhattan, composed of 19 nurses. This feature was added in 1902. The following diseases are treated by the school nurses: Pediculosis, conjunctivitis (*never* trachoma), ringworm, scabies, impetigo, favus molluscum contagiosum. Through the work of the nurses many children remain in school who would otherwise be excluded.

For the routine examination of eyes and ears alone, necessarily the specialist's services are most valuable; next, those of the general physician; and, lastly, those of the teacher. However, for practical reasons, undoubtedly the Allport system is the most feasible for obtaining results. The majority of teachers in our secondary schools being women, true to the instincts and traditions of their sex, they for the most part uncomplainingly assume any added burdens which boards of education and superintendents, mostly men, true to the instincts and traditions of their sex, thrust upon them. This system, with which doubtless most of you are familiar, requires the use by the teacher of Snellen's test types, and the answering by her, through information gained from the pupil or from observation, of the following questions: First—Does the pupil habitually suffer from inflamed lids or eyes? Second—Does the pupil fail to read a majority of the letters in the No. 20 line of Snellen's test types with either eye? Third—Do the eyes and head habitually grow painful after study? Fourth—Does the pupil appear to be cross-eyed? Fifth—Does the pupil complain of earache in either ear? Sixth—Does matter (pus) or a foul odor proceed from either ear? Seventh—Does the pupil fail to hear an ordinary voice at twenty feet in a quiet room? Eighth—Is the pupil frequently subject to colds in the head and discharges from the nose and throat? Ninth—Is the pupil an habitual mouth-breather?

In case of affirmative answer to any of these questions, the teacher sends a card of warning to the parents. Dr. Cronin says that in New York 50 per cent. of children whose parents were notified of their showing defects of vision, were fitted with glasses.

What can medical inspection accomplish for the pupil? Alone considering eye and ear, it can remove the chief handicap to the obtaining of a common school education, and can lay the foundation in physical health for further years of study and the practical duties of life. For the myope it can create a new heaven and a new earth. Dr. Allport, in his address before the Minnesota Academy of Medicine, February 6, 1895, quotes M. Francesque Sarcy, the French critic, a high-grade myope whose experience doubtless many here present have duplicated.

"I was born myopic. One day prompted by a spirit of mischief, I got hold of the big silver spectacles which my father wore, and clapped them on. Fifty years have passed since then but the sensation I experienced is keen and thrilling to this day. I gave a cry of astonishment and joy. Up to that moment I had seen the leafy dome above me only as a thick, green cloth, through which no ray of sunlight ever fell; now, Oh wonder and delight! I saw that in this dome were many brilliant chinks; that it was made of myriad separate and distinct leaves, through whose interstices the sunshine sifted, imparting to their greenery a thousand forms of light and shade. But what amazed me most, what enchanted me so that I cannot speak of it to this day without emotion, was that I saw suddenly, between the leaves and far, far away beyond them, little glimpses of the bright, blue sky."

By the correction of hypermetropia and astigmatism, the nervous, inattentive, ungovernable pupil, with constant complaint of headache, may be veritably transformed. Like marvelous transformation often follows the removal of adenoids, with correction of mouth-breathing, with its attendant anemia, malnutrition, irritability, and dullness.

Medical inspection will discover children of marked mental deficiency, who, removed to special classes, will acquire vastly more and quicker than could they in the regular grades. The child's whole mental, physical, and moral constitution will be safeguarded by thorough and competent medical inspection; inherited tendencies will be combated and present vices of constitution corrected. There is no limit to the good it can accomplish within the beneficent possibilities of medical science.

What can medical inspection do for the public? It can, and will reduce marvelously the prevalence of contagious disease and the mortality therefrom. Reason would dictate what experience proves—that medical inspection, in its public health function, finds wider scope in the large centers of population, with their overcrowding, poverty, and filth. The Massachusetts State Board of Health, as quoted by Somers, enumerates three new factors in the suppression of epidemics of diphtheria,—antitoxin, bacteriological examinations, and, last and most potent, daily medical inspection of the public schools. In Boston, during fourteen months ending December 31, 1895, 77 cases of diphtheria were found in their seats at school. In Newark, N. J., 13 cases were found in four months. In Chicago in four months, 233 schools were visited, and 1,417 cases of diphtheria found. From January to May, 1901, 401 cases of scarlet fever were found in the schools of Chicago. In Boston, in 1900, 23 cases of diphtheria were discovered in the schools. In Philadelphia, 231 cases of diphtheria were found in the schools, which cases led to the detection of 745 other cases in the homes.

The above facts are sufficient to suggest the vast possibilities in medical inspection for the mainte-

nance of public health and the reduction of mortality. Abroad, inspection of the eyes of school children has been practised, in isolated cases, since the first year of the nineteenth century. Risley, in Norris's and Oliver's System, gives an epitome of the results of such inspection, the most important being those of Cohn from the examination of 10,000 school children of Breslau in 1865-66. Risley states that up to 1897 the eyes of 200,000 children had been examined by competent persons.

Complete medical inspection, in the United States, is of twelve years' standing. Boston, led thereto by an epidemic of diphtheria, instituted medical inspection in the public schools in 1894; New York, in 1897; Philadelphia, in 1898; Chicago, in 1900. Other cities mentioned by Somers where it is in effect are Orange, N. J.; Brookline and Newton, Mass.; Jersey City, Asbury Park, Milwaukee, Minneapolis, Salt Lake and Cleveland. There are recent references in medical literature to its adoption in Cincinnati and Kalamazoo. Doubtless it has been instituted in many others. Two states, Connecticut and Vermont, have enacted laws requiring partial inspection; Connecticut requiring examination of the eyes only, by superintendent, principal, or teacher; Vermont requiring examination of the ears also, and fixing a stated time, September of each year, for such examination. Dr. Allport informs me that, if the present Massachusetts legislature has not already passed a law similar to the Vermont law, it will do so before the close of the present session.

Medical inspection of the public schools has had a nominal existence in Lincoln since December, 1901. For general medical inspection, the voluntary emergency system prevails. Inspectors are not paid for their services, and they are subject to the call of their respective principals. Routine, individual inspection of every pupil is not required. Two physicians, appointed by the Board of Education, together with the President of the Board of Health, constitute the Board of Medical Inspection of Public Schools, which board, with the approval of the Board of Education, appoints an assistant inspector for each public school. It is the duty of the chief inspectors to visit, at least twice yearly, their respective schools, in order to determine the sanitary conditions prevailing therein; to aid assistant inspectors in the event of any formidable epidemic, and to receive weekly reports from the assistant medical inspectors. Experience has here, as elsewhere, already demonstrated the inefficiency of a voluntary emergency system of medical inspection. For the examination of the eyes and ears of children in the public schools, through the effort of Dr. W. M. Cowgill, the Allport system was adopted last fall, and two specialists were assigned to each school to direct the work of the teachers. It is, as yet, too early to obtain a report of the first year's work.

In the fall of 1903, on my own initiative, I began a systematic individual inspection of the pupils of the Everett School; the following year like work was done in the Capitol School, and this year, in the Park. In each of these schools I have had the hearty co-operation of the principal, Misses Sarah Rands and Anna Tibbetts, and Mrs. Mary B. Fleming. These three schools are fairly representative of the school population of Lincoln. The Capitol School is attended largely by children from well-to-do families, and has, probably, as little foreign admixture as any. The Everett School, with 1 2-3 as many children of foreign parentage, draws much more largely from the poorer classes. The Park School is more than one-half of foreign parentage, predominantly German.

Lincoln is a healthy city. We have no slums, no overcrowding, little real poverty. W. C. Rohde, Health Officer of Lincoln, has kindly furnished me with the mortality records for the past five years. Placing the population of Lincoln at 42,000 in 1901 (the census of 1900 showed 40,000), with an estimated increase of 2,000 each year, the death rates are as follows:

1901,	10.42	to each 1,000 of population.
1902,	7.07	to each 1,000 of population.
1903,	8.39	to each 1,000 of population.
1904,	8.56	to each 1,000 of population.
1905,	7.94	to each 1,000 of population.

During the past five years there have been 323 cases of diphtheria quarantined, with 44 deaths, or 13.6 per cent.; and 264 cases of scarlet fever, with 1 death, or .3 of 1 per cent.

Not being familiar with methods of medical inspection elsewhere employed when I entered upon this work, nor with the Allport System, the plan which I then formulated was not as comprehensive as I now would make it. My record contains name, age, nationality, grade, sex (when name not distinctive), race; the results of eye-tests with Snellen's test types, the eyes being examined singly, except in the First Grade; tests of hearing, with improvised acoumeter at increasing distance, each ear being tested with the other covered and the eyes shut; inspection of throat, lids, posture, general appearance; also, answers to questions as to the fact of headache, its frequency, severity, and location when present. The examinations were made singly, in an unoccupied room. From 20 to 25 children were examined in a morning's work. In all, 1,018 children were examined—262 at the Everett, 414 at the Capitol, 342 at the Park. Of these, 519 were boys and 499 girls. The percentage of children of foreign parentage was 21 in the Capitol, 35 in the Everett, and 55 in the Park. Forty-five per cent. of children in the Park School were of German parentage; in fact, of foreign parentage, German largely predominates in all the schools; next following in order, Swedish, English, and Bohemian.

In the Everett School were found the following percentages for the various defects: Myopia (20-40 or less), 13; defective hearing, 9; hypertrophied tonsils, 21; spinal curvature, 53; appearance of poor health, 16; mouth breathing, 3.6; deafness associated with hypertrophied tonsils, 56.

In the Capitol School were found the following: Myopia (20-40 or less), 9; defective hearing, 7; hypertrophied tonsils, 22; spinal curvature, 66; appearance of poor health, 18; mouth breathing (all suspicious cases), 9; deafness associated with hypertrophied tonsils, 23.

In the Park School were found as follows: Myopia (20-40 or less), 11.6; defective hearing, 8; hypertrophied tonsils, 17; spinal curvature, 54; appearance of poor health, 8; mouth breathing, 12; deafness associated with hypertrophied tonsils, 10.

Myopia is the only refractive error of which my tables give an accurate estimate. To arrive at an estimate of the relative prevalence of other refractive errors we may include, as presumably associated therewith, cases of persistently recurring and severe headache induced by study; cases which wear glasses, but in which the test type fails to reveal myopia, and cases of severe chronic conjunctivitis

In the Capitol School there were found 21 cases of follicular conjunctivitis, 33 cases of headache, and 17 who were wearing glasses without discoverable myopic error; a total of 71 cases, or 17 per cent. of the whole school.

In the Park School were found 11 cases of follicular conjunctivitis, 32 of headache, and 6 wearing

glasses without discoverable myopic error; a total of 49, or 11 per cent.

Risley, from result obtained from examination of the eyes of all children in the public schools of Philadelphia by specialists, without the use of a mydriatic, but with attention to every detail helpful to accurate results, puts the ratio of normal vision and of the various refractive errors as follows: Emmetropia, 11.19 per cent.; hypermetropia, 31.23; hyperopic astigmatism, 42.81; myopia, 2.68; myopic astigmatism, 11.02; mixed astigmatism, 1.07.

According to this ratio my tables should give 61.40 per cent. of errors other than myopia.

Allport gives the percentages found by Erismann of St. Petersburg, in 1871, of myopia and hypermetropia, in his examination of the eyes of 4,368 school children.

Class.	1	2	3	4	5	6	7	9	10.
Myopia	13.6	15.8	22.4	30.7	38.4	41.3	42.	49.8	41.7
Hypermetropia	67.8	55.6	50.5	41.3	34.7	34.5	32.4	36.2	40.

This table shows the steady increase of myopia in ascending grades, and a less marked decrease in hypermetropia. It, as well as Risley's table, stamps my percentages of refractive error other than myopia as untrustworthy.

Of all refractive errors, myopia is the one detection of which is most important, because of its progressive and dangerous character. To point its progressive character. Risley, in Norris's and Oliver's System, quotes Cohn's figures: In 5 villages, 1.4 per cent. of myopia; in 20 elementary schools, 6.7 per cent. of myopia; in 2 higher girls' schools, 7.7 per cent. of myopia; in 2 intermediate schools, 10.3 per cent. of myopia; in 2 realschulen, 19.7 per cent. of myopia; in 2 gymnasia, 26.2 per cent. of myopia; in the university, 59.5 per cent. of myopia.

My percentages of defective hearing, 9, 7, and 8, fall much below the only percentage I can find based upon a large number of cases—20.33 per cent.—the result obtained by six observers in eastern cities, quoted by Somers. My percentages of spinal curvature, from the slightest detectable to real deformity, obtained by inspection alone, without removal of clothing, 53, 66, and 54, are sufficiently large to indicate the need of other methods of seating, writing, etc., than at present obtain in our schools. Contrary to expectation, and to results obtained elsewhere, boys showed curvature in slightly greater number than girls. The percentages in the Everett and Capitol schools of children having the appearance of poor health are almost identical 16 and 18 per cent. The small percentage, 8 per cent., at the Park is noteworthy. These children, whose parents were German colonists in Russia, are unmistakably better nourished and more robust than native American children. It seems as though the process of natural selection through rigors of climate and deprivations of poverty must in part account for the sturdy health of these children. Certainly every, to us, essential law of hygienic living is violated in their homes. As might be predicated without investigation, the children of the Capitol School have received far more medical attention than those of the Park, there having been performed on them 6 tonsillotomies, 5 adenoid operations, 1 mastoid operation; 22 were wearing glasses and 4 had worn them; the eyes of 9 others had been examined. At the Park School 4 were found wearing glasses and 2 had had operations performed, on eye and nose respectively in each case for accident.

No record was made of skin disease brought to my attention by the principals, of which there were a few. No systematic investigation was made as to the prevalence of skin disease, although very little, if any, present on visible portions of the body, could have escaped attention. No special inspection of teeth was made, a serious omission.

A study of the colored population of these three schools shows 15 in the Everett, 3 in the Capitol, and 6 in the Park—a total of 24, 12 boys and 12 girls. Nine of the boys and 6 of the girls showed normal vision and hearing. Five were myopic and 3 showed defective hearing (one being almost totally deaf); or 20 per cent. were myopic and 12 per cent. deficient in hearing, percentages higher than for other children. The small number of children examined renders these percentages of little value. The only statistics I have found relative to colored children are those of Callan of New York, quoted by Allport, who examined 457 negro children between five and nine years of age, and found 2.5 per cent. myopic.

Let me instance a few special cases. In the Everett I found P. W., aged 14, Fourth B Grade, daughter of a well-to-do saloonkeeper; vision in right eye 20/50 and in the left, 20/100; almost totally deaf in the right ear; tonsils large and pitted; mouth-breather; notched teeth; very unhealthy in appearance. When notified of her daughter's condition, the mother visited the school and soundly berated the principal and myself (who fortunately was absent) for presuming to suggest the presence of any defect. In this case nothing has been done. Presumably unfortunate domestic conditions eventuating in the divorce of the parents may be partially responsible for the neglect. In the same school a feeble-minded boy, who, because of his irritability, was a constant menace to school discipline, was, through the cooperation of principal, medical inspector and sensible parents, removed to the Institute for Feeble-Minded at Beatrice, where he is contented, docile, and is making marked progress. In default of visits from the chief inspector of the district, the principal and myself addressed to the Board of Education a statement regarding the disgraceful condition of the toilet rooms, especially the boys'. This was signed by the principal, the janitor, and myself, and was sent to the board. No action was taken by the board. Perchance the information and suggestion did not emanate from the proper source.

In the Capitol School was found an epileptic whose attacks were infrequent, but which occasionally occurred in school. The principal had already called the attention of the superintendent to this case, who had reported the parents unwilling to have the boy removed from school. He is still in school, now seventeen years of age, and in the Eighth Grade. The first day of school this year he had an attack; but he does fairly well in his studies, and is docile. He should be in a special class. A feeble-minded child in this school should have been sent to Beatrice, but in this case the necessary adjunct to successful accomplishment—sensible parents—was wanting.

At the Park School, during the present year, one boy appeared for the routine examination presenting clinical evidence of diphtheria. Three cases of scabies, in children just returned from the beet-fields, were excluded, and a visit made by myself to the home to instruct in the treatment. Examinations at the Everett School were, during the first half of the year, conducted in a cellar with brick walls and floor. Later, this being required to accommodate a class of beet-field children, I withdrew to a darker and mustier cellar, so poorly lighted that the work could be carried on only on sunny days. Being situated beneath the kindergarten, extreme patience and ingenuity were required to sandwich in the tests for hearing between the marching, singing, and shuffling of the kindergartners.

REMOVAL OF AN INTRALIGAMENTARY CYST AND BILATERAL OOPHORECTOMY DURING EARLY PREGNANCY WITHOUT INTERRUPTING GESTATION.*

By ABRAM BROTHERS, B.S., M.D.,

NEW YORK.

ADJUNCT PROFESSOR OF GYNECOLOGY, NEW YORK POST-GRADUATE MEDICAL SCHOOL; VISITING GYNECOLOGIST BETH ISRAEL HOSPITAL.

Mrs. B. L. first came under my notice for her present trouble on August 3, 1903. She was twenty-eight years old, married twelve years, and had given birth to four children, the youngest being eight months old. Her confinements had been normal with the exception of the last, in which dystocia was due to a breech labor. Her puerperal weeks had been without accident, and she looked like a fairly healthy type of woman. Her menses, since her last childbirth, had come on when her baby was four or five weeks old, and had been rather profuse. Recently she had begun to complain of a left-sided abdominal pain, which had a tendency to spread over to the right side. Excepting a moderate leucorrheal discharge, she complained of nothing more. Bimanual examinations revealed a normally placed uterus, somewhat large, and, behind it, a soft, fluctuating tumor about the size of an apple, which was regarded as an ovarian cyst.

On December 2, 1903, the patient reported again. Her periods had recurred at regular four-weekly intervals, had become more profuse, and were associated with pains all over the abdomen and back. The pain was now present in the intermenstrual epochs and was becoming more severe over the right side. The tumor lay quite low in Douglas' sac and had distinctly increased in size. She rejected operation.

I lost sight of the patient for more than a year. In the early part of December, 1904, she called again. She was seven weeks pregnant. The tumor seemed to be larger in size, and she readily submitted to my proposition that she be operated upon.

On December 19, 1904, at Beth Israel Hospital, laparotomy was performed through a suprapubic, transverse incision. On the right side and behind the uterus the intraligamentary cyst presented to-night was found and removed in one mass with the intimately connected Fallopian tube and cystic ovary. The ovary of the left side was found enlarged and microcystic. It had a rather broad attachment to the posterior surface of the broad ligament, which was clamped and the ovary exsected. The stump, was sewed over, and it is likely that a small fragment of the cortex of this ovary may have been left attached to the broad ligament in the suture. Convalescence was uninterrupted and the wound healed by primary union. The patient left the hospital after several weeks, pregnancy not having been disturbed.

She went on to term and was delivered of a fine baby, which is now ten months old. Menstruation has been fairly regular since she left the hospital, and, on one occasion, she called in great alarm at my office to learn whether, in spite of my assurance to the contrary, pregnancy had not again set in. Local examination negatived this suspicion. She last saw her menses on April 28, 1906, and they lasted five days. The abdominal wound showed at no time, during the pregnancy or since, any sign of weakening or hernia. The patient is still nursing her child.

*Read at the special meeting of the Deutsche Medizinische Gesellschaft, in honor of Professor Dührrsen, on May 15, 1906.

This case is reported in order to emphasize three features of interest, all of which may be of practical value:

1. The comparatively small risk of doing intraperitoneal surgery on the pregnant woman.

2. The value of the transverse incision in order to guard against hernia in cases of progressive pregnancy.

3. The practically complete removal of both ovaries was not followed by disturbance of the impregnated ovum.

Regarding the first proposition, the question naturally suggests itself as to whether it would not have been wiser to have artificially interrupted the pregnancy and then to have proceeded to the removal of the tumor. While I have, on occasion, followed this method myself, I think the consensus of gynecological opinion is to avoid double work by attacking the chief factor at once, especially as by modern methods this can be done with comparatively little danger. Thus Heil has reported 241 ovariotomies done during pregnancy, with a mortality of only 2 per cent. On the other hand, it is highly dangerous to leave such tumors undisturbed until labor has set in. McKerror collected 720 cases of this kind, and records a maternal mortality of 21 per cent. In my studies made ten years ago, I found that ovarian cysts and those of the broad ligament complicating pregnancy at term showed a maternal and fetal mortality of about 50 per cent. Of course this fearful mortality rate applied only to the older statistics collected up to that time. The risk of interrupting pregnancy is considerably augmented when operations are done in the advanced months of gestation. Thus, in recent times, Audebert finds that 60 per cent. of these cases are followed by an interruption of pregnancy.

During the past eighteen months I have done five laparotomies on pregnant women, the pregnancy being interrupted in one of the cases. Briefly narrated, the cases were as follows:

Case I.—A young recently-married woman was willing to be operated upon on condition that every effort should be made not to deprive her of the possibility of maternity. From the uterus—in an early stage of pregnancy—grew six sessile pedunculated myomata, the largest reaching as high as the umbilicus. Multiple myomectomy was done and the patient left the hospital after three or four weeks with the pregnancy undisturbed.

Case II.—In this patient (who was also in an early stage of pregnancy), an ovarian cyst, the size of a football and with twisted pedicle, was successfully removed without disturbing the pregnancy.

Case III.—This was the case reported to-night. An intraligamentary cyst and both ovaries were removed in the seventh week of pregnancy and the patient carried her child to term.

Case IV.—This intervention was followed by spontaneous abortion. Laparotomy was done for an intraperitoneal purulent collection which had formed about the fimbriated extremity of a left-sided pyosalpinx. The diseased adnexa were removed from this side. On the right side another pus tube was discovered and removed. The corresponding ovary was exsected in part only. Drainage was deemed necessary in this case through the lower angle of the abdominal wound. On the third day a small fetus with placenta was expelled from the uterine cavity. Convalescene was otherwise undisturbed.

Case V.—This was a case of appendicitis operated on during the third month of pregnancy in a primipara, without interfering with the gestation.

I have resorted to the transverse suprapubic inci-

sion of Pfannenstiel several dozens of times without mishap. In this country I think that Stimson has made use of this incision in the largest number of reported cases. Very rarely, because of the need of more room, I have been obliged to add a median longitudinal incision, converting it into an anchor-shaped wound. This has not been followed by any marked interference with the proper healing of the wound. While the applicability of the incision has its limitations, I have done a large range of operations by its means: hysterectomy when the size of the uterus was not prohibitive; operations on tubes, ovaries, and intraligamentary tumors; ventrofixation and appendectomy. In two instances at least I removed fairly large pus tubes. In one case I removed through this incision a multilocular ovarian cyst on one side and an intraligamentary cyst on the other. Tumors the size of two closed adult fists and larger are readily removed through this transverse cut.

In the case reported to-night I believe that the idea of the transverse incision was a particularly happy one, because the woman was in an early stage of pregnancy and had before her seven months of progressively increasing tension on the abdominal scar. At no time during pregnancy was there any evidence of thinning of the scar, and at present, long after delivery, there is not the remotest suggestion of a hernia.

Finally, it seems to me that this case deserves to be placed on record as one in which the removal of both ovaries was not followed by an interruption of the pregnancy. I make this assertion deliberately and advisedly, with a full knowledge of the fact that a small fragment of the cortex of one ovary was left in the pedicle attached to the broad ligament.

Mandl states the theory of Born to be that the corpus luteum of pregnancy has as its function the implantation of the impregnated ovum in the uterine mucosa, with its further growth and development safely controlled. More than ten years ago Sokoloff described atrophic phenomena in the uterine muscle following castration, and assumed that this atrophy was due to trophic disturbances in the nerves and nerve centers. He first castrated animals in the second and third weeks of pregnancy. At the end of two months the animals were killed, and while no trace of the fetus could be found, atrophic changes were discovered in the uterine structures. From this he concluded that after castration a degeneration of the embryo ensues, terminating in its complete absorption.

Fraenkel, whose views are accepted by Fleck and others, goes further. He attributes menstruation to the influence of an internal secretion of the corpus luteum. He regards the corpus luteum as a glandular structure with a special secretion formed in regular cycle periods, which supplies a trophic impulse to the uterus. One of the results of this influence he claims to be the retention *in utero* of the impregnated ovum. From his experiments on rabbits he lays down the law that "the retention of the impregnated ovum is dependent on the presence of the ovaries." Animals castrated shortly after intercourse fail to become gravid at all. He draws the practical conclusion, in the human female, that ovariotomy should be postponed until the latter end of pregnancy, or at least "until the corpus luteum has fulfilled its function."

While Halban is inclined to oppose Fraenkel's theory in regard to the corpus luteum, he seems to agree with him in regard to the influence of the ovaries in controlling the implantation of the fructified ovum.

On the other hand, Skrobansky, in about one-third of his experiments on gravid rabbits, found that if, between the tenth and sixteenth days, the ovaries were carefully removed, pregnancy would continue undisturbed and delivery take place at the right time. These experiments would seem to dispose of the question definitely. The author adds, however—and this strikes me as illogical—that the removal of the corpora lutea, leaving the ovaries otherwise intact, should render a continuance of gestation impossible.

From observations and studies on the human subject, Zacharias concludes that the persistence of pregnancy in those cases in which double oophorectomy had been performed is explained by the presence of small portions of ovarian tissue left in the stump. He thus accounts for a case of Pozzi. If this explanation does not stand fire, he still clings to the idea of an accessory ovary having been overlooked at the time of operation. Prof. Elis Essen-Möller, however, in reporting a case in which pregnancy went on to term after bilateral oophorectomy done in the early period of gestation, distinctly denies both of these contingencies in his particular case. The same is true of Kosmiuski's case.

I submit the report of this case to your consideration for what it is worth. A third ovary was certainly not present. Whether the minute fragment of ovarian tissue left in the stump sufficiently explains the retention of the fructified ovum *in utero* with the persistence of menstruation since, I leave to you to determine.

Note.—Since the above was written the following facts have come to the writer's notice: In 1895 Mainzer was able to collect statistics of sixteen cases of double ovariotomy done during pregnancy, in which gestation was interrupted, as a result of the operation, in five. Orgler, in 1902, added fourteen cases, with one interruption of pregnancy. Graefe, this same year, added two more cases, with one interrupted gestation. In 1904 Heil collected eleven additional cases, with two interrupted pregnancies. Adding Essen-Möller's and Kosmiuski's cases, we have two more cases in which pregnancy was not disturbed. Besides the writer's case reported in this paper, Dr. G. M. Edebohls has, in an unpublished case, also done bilateral ovariotomy without interrupting the associated pregnancy. Up to date the number of double ovariotomies done during pregnancy amounts to forty-seven cases, with interruption of pregnancy in nine, or 19 per cent. of the cases. Finally, it may be of interest to note that the mortality of ovariotomy during pregnancy was placed by Fehling at 5 per cent. Orgler, by studying later statistics, was able to reduce the death-rate to 2.7 per cent., and Graefe, still later, reduced it to 2.3 per cent.

112 East Sixty-first Street

A CONTRIBUTION TO THE ETIOLOGY OF OTITIS MEDIA ACUTA SUPPURATIVA POST MORBILLOS.

By GUSTAV BAAR, M.D.,
PORTLAND, OREGON.

In March, 1904, there came into my office the farmer B., who had just come with wife and five children from a place in Colorado, situated at an altitude of about 8,000 feet, to Portland, with an altitude of about 100 feet. He reported the following: Eighteen days ago his daughter Clara, 11 years old, became ill with the measles; two days later his daughter Anna, 13 years, and at the same time his daughter Lily, 9 years; after three days more

Margaret, 2 years, and after three more days also his 7-year-old Francis, became ill in the same manner. After the disappearance of the eruption all the children were seized with earache, which lasted about one day, following which the ears began to discharge.

The following report on the course of the five cases lays no claim to scientific preciseness. The fact that it proceeds from the day-book of a busy general practitioner may excuse many a fault in form.

I. Anna (thirteen years old).

May 15.—The child for the last week has had pains behind her left ear and purulent discharge. The mastoid process is very painful on pressure and edematous, as is also the region before the auricle. Temp., 101.8°; pulse, 120. Right ear normal. At the left the exterior auditory meatus is narrowed by the swelling of the anterior and posterior wall; there exists fœtor ex ore. Treatment: Compresses with Burow's solution.

May 16.—Considerable pain during the night, ceased this morning. Temp., 99.2°. Purulent discharge profuse. Edema has almost disappeared. Only some sensitiveness on pressure.

May 17.—Last night temp. 104°. Mastoid process again painful. Secretion of pus profuse. Temp. in the morning, 99.6°.

May 18.—Temp. during the night, 102.0°; in the morning, 99.8°. Mastoid process is still painful; secretion profuse. The examination of the pus taken from the depth of the exterior auditory meatus shows the following: Numerous pus corpuscles, moderately numerous cuboidal cells, now and then mucus corpuscles, moderately numerous diplococci, resembling the gonococci in shape and size, without capsules, singly or in groups and in chains of from four to six pairs, mostly intracorpuscular, now and then also extracorpuscular; otherwise no other cocci nor bacteria.

May 19.—Swelling and painfulness of the mastoid process lessened. Patient slept well. Temp., 98.8°. The membrana tympani bulging out and swollen in its posterior part; in its anterior part two granulations; secretion diminished. Treatment: Drainage with gauze soaked in Burow's solution.

May 20.—Left membrana tympani red and swollen; mastoid process still painful, little purulent secretion. The stab and streak culture made with the pus of the ear on Koch blood serum showed a broad streak consisting of white pointed colonies, which when melting together, appear yellowish; positive to Gram's stain; but among them are groups of cocci of the same shape and grouping as the former, which are, however, negative to Gram.

May 21.—Yesterday afternoon temp. 101.0°; this morning, 98.8°. The point of the mastoid process is still painful upon pressure, the depth of the exterior auditory meatus and the membrana tympani is still red and swollen. Secretion slight.

May 23.—Temp., 101.2°. Mastoid process still sensitive. Secretion slight.

May 24.—Temp., 100.4°. Mastoid process still painful. Membrana tympani red and swollen; from the perforated spot arises a small granulation.

May 25.—Temp., 101.4°. Membrana tympani not swollen; but little secretion; now and then pains behind the ear.

May 28.—The patient spent a sleepless night in consequence of pains behind the ear; there is nausea; the tongue is coated. Temp., 103.5°. But little secretion. Operation by Dr. Coffey. Opening of the mastoid process and of the antrum with evacuating of a few drops of pus; curettement of the cavum tympani through the exterior auditory meatus. The pus evacuated by the operation consists of pus corpuscles, mucus corpuscles, and blood corpuscles, as also of cuboidal ephithelia; no cocci, no bacteria.

June 8.—Discharged as cured.

II. Margaret (two years old).

May 16.—Otitis media acuta suppurativa bilateralis without complications. Treatment: Irrigations with solution of boracic acid.

May 18.—Temp., 100.0°. On both sides purulent secretions. Membrana tympani red and swollen. In the auditory meatus vesicular eczema. With Margaret the pus consists of numerous pus corpuscles; cuboid cells and mucus cells; numerous diplococci, singly, in chains of from four to six, or in groups, mostly intracellular, but also extracellular; in shape and size they are like gonococci. Otherwise in the pus no other cocci nor bacteria; discolored by Gram's stain.

May 19.—Temp., 98.7°. Still profuse secretion on both sides; membrana tympani red and swollen.

May 20.—Temp., 99.0°. Still secretion on both sides; membrana tympani very red on both sides. The streak-culture made with the pus of the ear on Koch blood serum, shows after eighteen hours a considerable growth, consisting of white pointed protuberances which, when conglomerating, appear yellowish. Numerous cocci, singly, in pairs, or in short chains of from three to five pairs of the size of gonococci, mostly Gram-positive, a few Gram-negative.

May 21.—Temp., 100.4°. There is yet considerable secretion on both sides; membrana tympani on both sides red and swollen.

May 23.—On both sides considerable purulent secretion.

June 4.—Right side secretion moderate; left membrana tympani of normal color; no secretion. The mother reports that the child, for three days has had fever, coughed, and complained of pains on the left side of the chest. Temp., 105.0°. Dullness in left posterior inferior region.

June 6.—Temp., 103.5°. Pulse, 160. Respiration, 60-70. Pulmonary condition: Right posterior vesicular breathing; normal pulmonary sound; at the left posterior, dullness and distinctly bronchial breathing. Treatment: Inf. fol. digit. 0.3 = 180.0. Tablespoonful every three hours.

June 8.—Temp., 103.5°; pulse, 160; respiration, 80 (!). Pulmonary condition: Left posterior, bronchial breathing; left posterior below, lessened breath-sounds and complete dullness: Treatment: Injections of camphor oil; cold packs.

June 9.—Temp., 102.9°; pulse, 160; respiration, 72. During the night the patient was cold and quite blue in the face.

June 10.—Temp., 102.0°. Pulse, 160; respiration, 72-82. Pulmonary condition: Left posterior, absolute dullness, bronchial breathing, above and over the center of the scapula lessened breathing; right posterior normal pulmonary sound, vesicular breathing.

June 11.—Temp., 104.2°; pulse, 170; respiration, 80. Prolonged paroxysms of coughing. Pulmonary condition: Right: posterior-superior region, absolute dullness; posterior inferior region, relative dullness; breathing of the whole right side bronchial; left posterior, somewhat sharpened vesicular breathing; left anterior, at center tympanitic sound.

June 12—Nine A.M., temp. 98.0°; pulse, 160; respiration, 40. Patient was delirious and screamed all night. Pulmonary condition: At right posterior-inferior and at the level of the scapula the pulmonary

sound is clearer, the breathing sharp and vesicular; right superior-posterior still dull and bronchial. At left posterior the same condition as yesterday.

June 14.—Temp., 98.2°; pulse, 126; respiration, 40. Pulmonary condition: Pulmonary resonance, left posterior superior still somewhat dull, everywhere else cleared. Breathing posterior left superior, bronchial, at the level of the scapula vesicular.

June 15.—Temp., 97.5° = 98.5°; pulse, 120; respiration, 38. During the last thirty-six hours still some paroxysms of coughing; the ears began again to discharge. Pulmonary condition: Pulmonary resonance and breathing both normal, except a little dullness and lessened breathing at the right posterior inferior region. Later cured.

III. Lily (nine years old).

May 16.—Otitis media acuta suppurativa bilateralis, without complications. Treatment: Irrigation with solution of boracic acid.

May 17.—Mastoid process painful on both sides.

May 18.—Temp., 99.6°. Mastoid process on both sides painless, normal. Secretion at the right side diminished; membrana tympani red and swollen. Secretion at the left purulent; posterior half of membrana tympani bulged out and red; anterior half covered with pus. Treatment: Irrigation, dry dressing of auditory meatus and insufflation with boracic acid.

May 19.—Temp., 100.0°. Right ear: No secretion. Membrana tympani less red and swollen. Left ear: Secretion moderately purulent. Membrana tympani in the posterior region bulged out and red.

May 20.—Temp., 99.8°. Right ear dry. Left ear: Membrana tympani still somewhat red; secretion slight. The streak-culture made with the pus on Koch blood-serum shows, after forty-eight hours, yellowish, dome-shaped, scattered protuberances of the size of a pin's head and smaller; these consist of cocci, which are arranged singly, in pairs or in short chains, but mostly in groups and are Gram-positive. The secretion of the left ear shows in cover-slip preparations pus corpuscles, cuboid cells, leucocytes, detritus, but no cocci and no bacteria.

May 21.—Temp., 99.2°. Right side no secretion, left the posterior-superior quadrant of the membrana tympani is red, swollen, and bulged out.

May 23.—Right side no secretion, left side but little.

May 25.—Temp., 99.0°. Profuse secretion left side; mastoid process not sensitive; right ear dry.

May 27.—No secretion.

June 12.—Yesterday the patient was seized with considerable pain in the right ear which, on opening the mouth, increased in such a manner that she refused nourishment. The anterior wall of the exterior right auditory meatus is bulging; the posterior half of the membrana tympani is red. Temp., 100.2°. Patient complains of excessive pains in head and neck; vomiting. The membrana tympani is again perforated; there is renewed secretion.

June 14.—Temp., 99.8°. Patient vomits and constantly complains of headache. Right ear: Upper posterior wall of the exterior auditory meatus protrudes; posterior half of the membrana tympani considerably red and bulged out; in the anterior half there is a perforation. Profuse secretion. Enlargement of the perforation by paracentesis.

June 15.—Right ear: Mastoid process painful; profuse secretion. In left ear also profuse secretion. Temp., 9 A.M., 98.8°; 6 P.M., 100.0°.

June 16.—Patient spent a sleepless night; no appetite; tongue coated. Temp., 100.0°. Right ear: Mastoid process very painful on pressure; the covering skin red; excessive purulent secretion. In the depth of the auditory meatus the posterior superior wall is bulging out and red; pus oozing out of the anterior half of the membrana tympani. Left ear: Mastoid process not sensitive; membrana tympani pale; place of perforation in the anterior-superior quadrant, purulent secretion. Operation at the right side by Dr. Coffey. After opening the mastoid process about a teaspoonful of pus oozes out from its posterior-superior regions. While following this direction the dura is laid open, after which some more purulent fluid discharges. Drainage, dressing. The cover-slip preparation made with the pus issuing from this extradural abscess shows numerous pus corpuscles, moderately numerous red blood corpuscles, very numerous diplococci, singly and in groups, extra- and intracellular, apparently in capsules, discolored after Gram's method.

July 8.—Dismissed as cured.

IV. Clara (eleven years old).

May 16.—Otitis media acuta suppurativa bilateralis, without complication. Treatment: Irrigation with solution of boracic acid.

May 17.—Temp., 102.0°. No pains.

May 18.—Temp., 101.2°. Mastoid process at the right side is sensitive on pressure, also the region in front of the ear; depth of the right auditory meatus red and swollen; membrana tympani not visible. Mastoid process at the left side also sensitive on pressure. Perforation in the anterior-inferior quadrant of the membrana tympani; the patient is hard of hearing on both sides. Treatment: Drainage with gauze soaked in Burow's solution. The pus of the ear consists of numerous pus corpuscles, also numerous cuboid cells, moderately numerous leucocytes, excessive bacteria which, however, stain less in the aqueous methylene blue than the diplococci present in the pus. The latter have the shape and size of the gonococci, are individual or in oblong groups of fifteen to twenty, or in chains of three to eight, mostly intracorpuscular, now and then extracorpuscular; all bacteria are discolored after Gram's method.

May 19.—Temp., 100.0°. Right ear: In the depth of the exterior auditory meatus the posterior superior wall is pressed downward; mastoid process sensitive on pressure; secretion slight. Left ear: Membrana tympani red and swollen; in the anterior-inferior quadrant is a small perforation. Mastoid process more sensitive than the right; secretion unchanged.

May 20.—Temp., 100.2°. Mastoid process still painful on both sides. The streak-culture made with the pus on Koch blood-serum after twenty-four hours shows a wide growth, consisting of yellow and white pointed colonies. These consist of cocci which are arranged in groups, here and there in pairs and in short chains, mostly Gram-positive (a few Gram-negative). The cover-slip preparation made with the pus from the left ear shows numerous pus corpuscles, cuboid cells with large round nuclei, moderately numerous leucocytes, and a few red blood corpuscles but no cocci nor bacteria.

May 21.—Temp., 99.5°. Right mastoid process still painful, not the left; secretion at the right, but very little, at the left moderate; membrana tympani still red and swollen on both sides.

May 23.—Temp., 100.8°. Mastoid process at the right very sensitive, at the left only at the point. Secretion from the right ear very fetid, from the left moderate.

May 24.—Temp., 100.4°. Mastoid process at the right painful, not at the left. At the right ear the posterior-superior wall of the exterior auditory meatus in the depth is red and bulged out, the membrana tympani scarcely visible; the left membrana

tympani is still red and swollen; the secretion considerably decreased; the hearing better.

May 25.—The patient cried a great deal in consequence of severe pain in the right ear. Temp., 100.4°. Right ear: Depth of the exterior auditory meatus red and bulging; membrana tympani red and swollen; secretion moderate. Mastoid process very sensitive, the covering skin red and swollen. Left ear: Mastoid process not sensitive; membrana tympani on both sides red and swollen. Hearing improved.

May 26.—Temp., 100.4°; pulse, 140. Sleepless night in consequence of pains; right ear unchanged; left ear unchanged. Operation by Dr. Coffey. The incision behind the right auricle shows no pus; after opening the antrum there discharges about a teaspoonful of thick yellow pus. The cover-slip preparation from this pus shows numerous pus corpuscles, mucus corpuscles, leucocytes, cuboid cells, red blood corpuscles and cocci arranged in clusters of six to twenty, intra-and extracellular, or in pairs, or in short chains. Gram-positive.

June 8.—Discharged as cured.

V. Francis (seven years old).

May 25.—Temp., 99.5°. From left ear profuse secretion. Membrana tympani red and swollen, perforated in the lower half. The pus taken from the ear shows in its cover-slip preparation numerous pus corpuscles, leucocytes, and cuboid cells, as also mucus cells; a moderate quantity of cocci, individual or in chains, pairs, or in groups; intra- as well as extracellular; no other cocci nor bacteria. Gram-positive.

May 24.—Temp., 101.2°. On both sides profuse secretion.

May 25.—Temp., 101.5°. Right ear: Mastoid process red and swollen; sensitive on pressure; membrana tympani red and swollen. Left ear unchanged.

May 26.—Temp., 101.0°. Right ear: Considerable secretion; membrana tympani red. Left ear: Considerable secretion; membrana tympani in the anterior-inferior quadrant perforated. In the right eye conjunctivitis.

June 4.—Left ear still shows moderate secretion, right ear dry; membrana tympani red and swollen only moderately. Later cured.

The bacteriological report on the cultures made with the pus taken from the depth of the exterior auditory meatus as well as the cultures made with the pus gained by the various operations was identical in all cases. Dr. Matson, the bacteriologist of the Oregon State Board of Health, was kind enough to place his report on the cultures sent to him, as well as the cultures themselves at the disposal for examination of Prof. Weichselbaum in Vienna. The report of Prof. Weichselbaum, to whom I here express my most sincere thanks, essentially agrees with Dr. Matson's. It says:

"The culture submitted showed: (1) A luxuriant growth on agar culture media, at incubator as well as room temperature. A few colonies attained a size of several millimeters in diameter and were protuberant, oblong, or round, sharply defined, shining, whitish or yellowish in tint. In general the appearance of the colonies as well as their growth in agar streak and stab culture completely corresponds with that of the staphylococcus pyogenes. (2) In gelatine-stab-cultures, growth along the inoculation stab with slow funnel-shaped liquefaction. (3) In bouillon cultures a diffuse exuberant turbidity. (4) Exuberant growth upon a potato in the form of a shining 'Rasen' with slight yellowish stain. The pigment formation was strong neither on agar culture media nor on potatoes and showed a faint orange tint.

"According to these facts said genus of bacteria which microscopically showed equally Gram-positive cocci, belongs to the species of micrococci and at best corresponds with a staphylococcus pyogenes with faint pigment formation and faint liquefying power for gelatine.

"Of the submitted cover-slips which were stained by Gram's method and with methylene blue, a few did not show any bacteria with certainty, probably because they already appeared considerably faded. In others, as for instance in the preparation from the cases of Francis and Clara, streptococci could be distinctly seen. The cover-slips which came from the culture media (Margaret, Lily, Anna) showed an absolutely similar appearance: Gram-positive cocci of the type of the staphylococcus pyogenes.

"From all these reports it follows that the submitted cultures have nothing to do with the *Micrococcus meningitidis cerebrospinalis* (*Diplococcus intracellularis,* Weichselbaum), and that surely in a few of the examined cases there existed infections with kindreds of the streptococci species. How far the submitted genus may be considered as its cause of the infections cannot be made out from the materials at hand."

The publication of this contribution seemed to me to be advisable for several reasons. It was not remarkable that measles occurred in all the five children of the same family; but it was very remarkable that in all of them there appeared an acute suppurative otitis media and not in such a mild form as was represented by Nadoleczny (*Jahrbuch für Kinderheilkunde,* Band 60). In three of these children the mastoid process, the antrum, and the cranial cavity respectively had to be opened on account of alarming cerebral symptoms which appeared in spite of the previous most painstaking antiphlogistic and antiseptic treatment, poultices, and drainage after careful irrigations of the exterior auditory meatus with warm solution of borax or instillation with peroxide of hydrogen and drying.

The appearance of this purulent inflammation of the middle ear, at the end of the second week of illness, seems to speak very much against the universal view, according to which the measle otitides are caused by the primary exanthem. The fact that in the pus taken from the depth of the exterior auditory meatus as well as in the pus taken under aseptic precautions during the operation from the antrum, mastoid process, and extradural abscesses, was found the same coccus—a staphylococcus—shows the latter to be the cause of the disease. Whether the infection with the staphylococcus was facilitated through lack of the proper care of the mouth or through the sudden emigrating of these children from a place situated at a height of 8,000 feet to one of only 100 feet, I must leave undecided. Whether the left pleuropneumonia and the right pleuropneumonia of the youngest child was caused by the same coccus, I have not been able to ascertain.

A Sphygmoscope for Determining Pulse Pressure.—Pal describes a rather complicated instrument which he has devised for the purpose of rendering it more easy to obtain satisfactory determinations of the systolic and diastolic blood pressure than is possible by any of the sphygmomanometers now in use. The principle consists in having a small column of petroleum dyed red contained in a horizontal capillary tube connected at either end with a system of tubes communicating with the manometer, the armlet, a pressure reservoir, and the pressure bulb. By means of a suitable arrangement of stopcocks it is said to be easy to deduce from the fluctuations of this column of fluid the values of systolic and diastolic pressure.—*Zentralblatt für innere Medizin.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, August 18, 1906.

A SUBSTITUTE FOR PASTEURIZATION.

THE artificial feeding of infants is still one of the great medical problems of the day, although the efforts of the last decade have contributed largely to its solution. It seems to be quite universally agreed at the present time that pure cow's milk furnishes the only efficient substitute for breast nursing, which must always remain the great desideratum, even though Dame Fashion and our modern mode of life decree otherwise. In view of the adaptability of cow's milk for the purpose indicated, great efforts have been made to secure this article of nourishment in as pure a form as possible, and to preserve it in this condition, particularly as regards its freedom from germs of a deleterious character. These efforts have extended in two directions. At first sterilization by boiling was regarded as a thorough method of obtaining germ-free milk, but although the bacteria were all killed, other changes took place, particularly in the albuminoid constituents, which rendered the milk unfit for food for infants. By pasteurization it was hoped that this would be avoided, until it was shown that certain harmless and necessary organisms were thereby killed, while the more dangerous spore-forming bacteria were not always destroyed, their proliferation being, in fact, occasionally favored.

But the demands of the pediatrists for a germ-free milk continued, and then the effort was directed toward enforcing extreme cleanliness at the dairies, including here the cows, the stables, and the attendants. This marked a great advance, but it has not entirely solved the problem, for although the entrance of germs from without is thus to a great extent prevented, it does not provide against the contamination from the cow's system. The milk of tuberculous cows is known to contain the specific germ, and until the diagnosis is established in any given case much harm may result. This would naturally suggest the employment of chemical agents in the milk, but their use has usually rendered the product unfit for the infant, on account of the taste as well as of other undesirable features. Peroxide of hydrogen has been largely employed for this purpose, and in many respects has been found to be very efficient; but it is necessary to devise some means for getting rid of the disagreeable taste imparted to the milk by this agent after its mission as a germicide has been accomplished. In this connection considerable interest attaches to the work of Much and Romer (*Beiträge zur Klinik der Tuberkulose*, Vol. V, No. 3), which was done at Behring's well-known experimental institute at Marburg. The method which these writers recommend for rendering milk practically germ free is briefly as follows: The milking is done directly into a sterile vessel containing a sufficient amount of hydrogen peroxide so that the proportion will be about 1-1,000, and then this is set aside for from six to eight hours, and finally heated in a water bath up to 52° C. After this has been done a special ferment is added in the proportion of from 0.5 to 1 gram per liter of milk, which entirely destroys the H_2O_2. The ferment in question is prepared from the blood of cattle according to a method devised by Senter, and has been called "hemase." The latter is free from hemoglobin and possesses a powerful catalytic action with an especial affinity for hydrogen peroxide. After two hours of treatment the milk is ready for use, and, if protected from the light, it may be kept for a considerable period. Its taste is claimed not to differ from pure, fresh milk, and it has been found free from germ growth even after twenty-one days.

The procedure referred to evidently exerts a very thorough and complete destructive effect on tubercle bacilli, for milk containing large numbers of these could, after being treated with hydrogen peroxide in the manner stated, be injected with impunity into the peritoneal cavity of guinea pigs. The writers claim that milk thus prepared will meet all the requirements demanded by pediatrists of a pure milk for infant consumption, and they also furnish sufficient data to prove the practicability of the method. Its cost has been calculated to be about one cent per quart, and although there are apparently many favorable and desirable features connected with their proposal it still requires both clinical and commercial tests, and these we look forward to. Methods of preserving milk by chemical means have never found much favor in this country, and the efforts to secure a germ-free milk have been extended rather to sanitary devices and continued cold. It may be impracticable, however, in certain instances to preserve milk by such means, and then the method advocated by the German investigators may be found to be applicable.

FOOD SCANDALS IN GREAT BRITAIN.

THE unanimity with which all the papers of Great Britain condemned the Chicago stockyards and meat-packing methods was remarkable, but, on the whole, not to be wondered at. Nevertheless, it would have been wiser on the part of some journals if they had not seized the occasion to extol the methods of British food manufacturers, and to "thank God that they were not as other men." This effusion of somewhat unctuous rectitude has been shown to be decidedly premature, for the annual report of the Chief Inspector of Factories and Workshops for Great Britain and Ireland has just been made public. That portion of the report which deals with the food factories of the United Kingdom is a very striking pronouncement. The English Government inspectors of those factories in which women are employed are of the female sex, and it is due to them that the true facts regarding the manufacture and handling of food products have been laid bare.

One Government inspector who has visited factories in Ireland, in which jam, confectionery, biscuits, condensed milk, and margarine are made, gives her opinion in an outspoken manner in regard to the lack of cleanliness observed in the majority of food-producing places in Ireland, but goes on to state that "Ireland has no monopoly of dirty factories, and throughout the United Kingdom the occupiers of food-making factories have too low a standard in general." Another inspector gives some revolting details as to the manufacture of sausages. She declares that the work is exceedingly disgusting and offensive to the senses, and states, on good authority, that it frequently disturbs the health of the women engaged in it. The same inspector says that in some of the sausage factories she has detected bad drainage and offensive emanations from the floor, due to the accumulation of offensive and decomposing animal matter, together with an intolerably fetid atmosphere and inadequate ventilation. An inspector of jam factories tells of the "disgusting smell" arising from the water in the tanks wherein jars were being washed for the reception of jam to be sold to the public. Chocolates and candy are "very much handled in the making" amid too generally prevalent dirty conditions. As a rule the workers are unable to keep themselves personally clean, as no arrangements are made for washing. The children and women workers—and this applies especially to Ireland—are seldom provided with overalls, and carry out their tasks in their oldest and dirtiest clothes. The state of the floors in some of the candy factories, according to this inspector, is offensively dirty; indeed, as the result of her Irish experiences, she declares that "the condition of the floors in very many food-making places is most unsatisfactory. In a margarine factory the floor was thickly covered with a black, greasy, sour-smelling mud;" and when the occupier was informed that the floor should be relaid with suitable material, carefully sloped, adequately drained, and means taken to prevent so much grease from falling on to it, he seemed astounded that this should be required, even though cleanliness could not be otherwise obtained.

Perhaps the most astounding feature of the situation is that as the law of the United Kingdom now stands there appear to be no effective legal remedies against such abuses. The Factory Acts do not touch such evils. What is really wanted is better and closer inspection; that is to say, that the number of inspectors be greatly increased, and that the condition of the workers should be bettered in every way; in fact, the whole matter of sweated wages should be attacked. The women employed in the British factories are, at the present time for the most part, so low down in the scale that nothing can be done to assist them.

At a meeting of the British Royal Sanitary Institute, held in Bristol on July 12, a heated discussion took place in regard to public abattoirs. During the debate on the subject a Mr. Bottomley asserted that if the public knew one-quarter of the evils that were perpetrated under the system of private slaughter-houses, the Chicago scare "would not be in it." He said he had known quite recently, in his own country district, a case in which a cow suffering from pulmonary tuberculosis had been slaughtered and eaten.

Enough, however, has been said on the question to show clearly that as regards food factories and slaughter-houses the United Kingdom is by no means without reproach; indeed, the revelations from Chicago will, in the long run, do good to both America and Great Britain. They will have attracted people's attention acutely to the subject, and will have so stirred up public sentiment that the proprietors of food factories will have no choice but to put their houses in order.

SCRAP TOBACCO.

The smoker has ever been a shining mark for the paper bullets of the unco guid, who have not scrupled to make use of all the ammunition they could induce medical science to furnish. For some reason or other the cigarette has had to bear the brunt of the onslaughts, though it has repeatedly been pointed out that when properly used by adults its power for harm must be a negligible quantity. There are possibilities attending the use of tobacco in any form, however, that probably are much more worthy of consideration than the stereotyped arguments of the anti-cigarette leaguers, and these have to do with the treatment to which the tobacco is subjected in the course of manufacture of the product that finally reaches the consumer's hand—and mouth. While the cigar butt fished from the gutter has not in this country become the article of commerce that it is in many European cities, notably Paris, where those who make a specialty of the collection of such relicts form a recognized branch of the guild of rag pickers, no doubt some unsavory enough components enter into the composition of the cheaper varieties of the tobacconists' commodities. But equally disgusting possibilities are not absent in the manufacture of wares of a much higher grade, and these both can and should be eliminated.

The fact that cigarmakers as a class are particularly prone to tuberculosis is well known; and also that in rolling the tips of cigars many workers are accustomed to moisten the end with saliva; but there is still another source of contamination that is not so widely recognized. Scrap tobacco is the trade name for the cuttings and fragments of tobacco leaves discarded by the cigarmaker and usually falling from the work table to the floor. This is a recognized by-product which is widely used and finds a ready market, but while lying about the workman's feet it is subjected to many vicissitudes, and is sure to become sullied with filth, if not contaminated with actual disease germs. Attention is directed to this source of danger to the public health by D. D. Stevens, who in a recent number of the *Medico-Legal Journal* describes a tour of inspection he made through a very large number of cigar factories. In one Southern State and adjacent islands he estimated that nearly 50 per cent. of the cigarmakers were tuberculous or syphilitic, and while in the North the workers as a class are less diseased their habits are no more cleanly than are those of the workmen in the South and in Cuba. The northern cigarmakers are mostly recruited from the ranks of the poorer class of immigrants, and consist largely of Poles, Russians, Italians, and Scandinavians. These people are very uncleanly in their per-

sonal habits and no attempt is made to prevent the material they work with from suffering in consequence. In one Harlem shop Dr. Stevens says he saw a cigarmaker at work who was suffering from advanced pulmonary tuberculosis, and who was constantly expectorating on the floor among the fragments of tobacco.

While no doubt in many of the factories the conditions of cleanliness and health of the employees are all that could be desired, it is certain that there is an urgent need for reform in this field. A majority of the male population are tobacco users, and should be safeguarded not only by regulations forbidding the sale of scrap tobacco under the present conditions, but also providing for the supervision of the health of the tobacco workers and controlling the sanitation of the workrooms. In the eye of the law the tobacco user should be regarded as deserving of as much protection as the consumer of food stuffs; and since it is certain that vast quantities of tobacco will always be consumed, it is the part of the authorities to see to it that whatever detriment to health attends its use is not added to by improper conditions of manufacture.

Senseless Cowardice.

A poor Syrian leper is living alone in a tent or hut somewhere in the wilds of West Virginia, driven there, so the newspapers report, we wish we could believe incorrectly, by the health officers of various communities in that and neighboring States. He was on his way to his far eastern home, where he hoped to end his days with his own people, but was discovered in a Maryland town, imprisoned for a time in a freight car, shipped east, then west, and finally dropped by the railway officials in a desolate region in West Virginia. There he now is, abandoned by his fellow men, and crying for some one to shoot him and end his misery. And this has happened in the year of our Lord 1906, in a Christian and civilized country. One can understand the fear of leprosy felt by the laity, who know nothing of the disease but the loathsomeness of its advanced stages and have exaggerated notions of its contagiousness, but it is inconceivable that the presence of a leper should throw educated medical men and health officers into such a panic of apprehension that they inhumanly cast him out from the community to perish in the forest. It was their duty to protect the unfortunate man and to quiet the unreasoning fears of the public, for they should know that the contagiousness of leprosy under ordinary conditions is slight. Yet the poor sufferer, a human being, has been treated by his fellows worse than a mangy dog. Surely it would be possible to have the man conveyed in a decent way to some place where lepers are segregated, there to live in comfort, provided with food and shelter. To toss him about from one place to another and finally to cast him out into the wilds is cruel and cowardly. Better almost would it be to heed the wretch's prayer and end his misery with a bullet.

The Diagnosis of Malignant Esophageal Stricture.

The recognition of esophageal stricture has been greatly simplified by the use of bougies particularly adapted for this purpose. This method, however, fails to afford any definite information as to the precise nature of the lesion, whether the constriction is due to spasm, to a diverticulum, to a cicatrix, or to a neoplasm. Spasmodic stricture is of course transitory, a diverticulum of the esophagus may usually be recognized in a fluoroscopic examination after the administration of bismuth subnitrate, but the differentiation between simple cicatricial stricture and that due to carcinoma is somewhat more difficult. In an endeavor to solve the latter problem, Marcou proposes a method which he has used successfully in several cases (*Archives générales de Médecine*, 1906, No. 15). An olivary bougie is passed into the esophagus and forced through the stricture, if this is possible, or otherwise merely pressed against it, and then rapidly withdrawn. The character of the deposit on the end of the instrument is then noted and examined. In one of his cases in which there was an indefinite dysphagia, the tip of the sound was bloody and presented a very foul odor. The deposit was stained with Loeffler's methylen blue solution and showed under the microscope, in addition to pus cells, numerous thick spirilla, while cocci and epithelial cells were present in only a limited degree. From the fact that such spirilla are commonly present in sloughing and especially in carcinomatous ulcerative processes, a diagnosis of malignant stricture was made and this was later confirmed. In another case a similar result was obtained and it would seem that in other doubtful cases the method could be employed with advantage to clear up the diagnosis.

News of the Week.

Failure of the Trypsin Treatment of Cancer.—A special despatch to *The New York Times* states that an inquiry made regarding the use of trypsin as a cure for cancer in the London hospitals has elicited unfavorable reports. The London Cancer Hospital has discontinued the use of the remedy, the surgeons having failed to obtain any beneficial results from it. In some hospitals the experiments are still proceeding, but apparently without expectation that they will result otherwise than have the tests at the Cancer Hospital.

A Tuberculosis Clinic has been opened at the Medical Department of the University of Southern California, Los Angeles, under the management of Dr. F. M. Pottenger. Its object is not only to treat free of charge the worthy poor, but more especially to teach methods of protection. Every case of tuberculosis reported will be investigated and the sufferer will be isolated or instructed in the duty of protecting others. Dr. Pottenger will be assisted by Drs. W. Jarvis Barlow, George H. Kress, and others, and the clinic will receive the support of the Antituberculosis League of Southern California.

The Study of Medicine in France.—According to statistics published in a recent number of *La Semaine Médicale*, the number of medical students in France is diminishing with considerable rapidity. The year 1906 shows a decrease of 1,044 over the year 1895, not counting foreign students, whose numbers had diminished 46.8 per cent.; that is, from 1,137 in 1895 to 604 in 1906. The falling off in foreign students is ascribed to the increasing strictness of the regulations for admission to the French schools, and the smaller number of native-born students is thought to be due in part to the same social conditions which have rendered the study of medicine less popular in Germany also, and in part to changes in the entrance examinations, military service, etc.

Care of the Insane in Illinois.—The Trustees of the Illinois Hospital for the Insane and the members of the State Board of Charities recently held a joint meeting, at which it was decided to begin at once improvements in the system of nursing and attention to patients with night supervision and medical attendance. The establishment of a modern pathological laboratory and the selection of a pathologist who will act also as instructor to the medical staff in special methods of examining cases and record keeping are planned. A training school for nurses is to be opened in September, with a three-year course.

Perils of Confectionery. — The *Lancet,* which is very fond of raking up all sorts of dangers to health in the affairs of every-day life, has recently pointed out the perils that lurk in the elaborate traceries of icing that adorn frosted bridal cakes, etc. This ornamentation is effected, we are told, by the "disgusting and filthy practice" of blowing the icing onto the cake through a tube applied to the lips of the pastry cook, and an instance is cited in which it was shown that a cook performing this function was the victim of specific disease of the mouth and throat.

Opposition to the Lourdes Pilgrimage.—The physicians and hygienists of France have been protesting strongly against the annual pilgrimage to Lourdes which takes place in August. The objectors state that the pilgrimage is not only a bad thing for the pilgrims themselves, but is also dangerous to the public health. Among the chief objects of denunciation is the piscina, in which sufferers are bathed. It is stated that the water, which is supposed to have healing efficacy, is not changed throughout the pilgrimage and is absolutely filthy. This, however, is denied by the clergy, who assert that the piscina is supplied by running water from the spring. Furthermore, it is objected, the trains conveying crowds of diseased persons, on which the most elementary rules of hygiene are violated, constitute a perpetual danger to the pilgrims, subsequent travelers, and the residents of the districts through which they pass. This is, of course, a matter within the control of the railway officials, who could insure the sanitation of the trains if they would.

Indiana Admonition Against Kissing. — The Indiana State Board of Health has decided to incorporate in its hygienic cautions to school children the recommendation neither to kiss nor to be kissed on the mouth.

Suit Against a Chiropodist. — The suit prosecuted by the County Medical Society against the negro proprietor of a so-called school of chiropody and dermatology was tried last week and resulted in the discharge of the defendant. He was arrested last May, charged with illegally issuing diplomas for his school, and the registered complainant was a man who had purchased one of these diplomas for $75. The court decided that there was no evidence that the certificate was fraudulent or unlawfully issued and that the school was organized under the laws of this State and was therefore not illegal. The alleged diploma conferred neither degree nor license, but was a certificate showing that the holder had completed the school's course of study in "theoretical and practical chiropody."

Yellow Fever in Mexico.—The dispatches from Mexico report the occurrence of twelve new cases of yellow fever, with seven deaths at Moyda and one new case and one death at Vera Cruz.

Accidental Deaths in Chicago.—Three hundred and thirty-six deaths were investigated in Chicago during July by the coroner, and of these more than 150 were due to violence; street car and railroad accidents led with 40 fatalities, followed by suicide with 33. During the month 24 individuals were drowned and but one death was charged to an automobile accident; 14 homicides were reported, and 11 deaths were due to the Fourth of July injuries.

A Peculiar Accident.—A physician residing in southern California is reported to have fallen out of bed, breaking one rib, dislocating another, and bending a third, without waking from sleep. He did not live in the earthquake belt, but probably dreamed that he did.

Pure Food Law Conference.—The pure food Board, which is made up of Dr. Harvey M. Wiley, chief of the Bureau of Chemistry of the Department of Agriculture; S. N. D. North, director of the Census Bureau, representing the Department of Commerce and Labor, and James L. Gerry, chief of the customs division of the Treasury Department, and which is formulating regulations for the enforcement of the pure food law recently enacted by Congress, has decided to grant public hearings to the food manufacturers who want to present their views as to the necessary regulations. These hearings will be held at the Department of Agriculture from September 17 to September 28, at which the manufacturers will be invited to express their views on the subject of the proper regulations.

The Canteen in Soldiers' Homes.—Commander-in-Chief Tanner of the Grand Army of the Republic has recently expressed the opinion that the passage by Congress of an act abolishing canteens from national soldiers' homes after next March was "unwise and a blow at real temperance, besides a restriction of the personal liberties of veterans of the Civil War that ought to be resented." A number of prominent officials of the organization have written General Tanner of their intention to bring the matter before the national encampment, which meets in Minneapolis.

Inspector of Nurse Training Schools.—The State Civil Service Commission will receive applications until September 4, 1906, for the position of Woman Inspector of Nurse Training Schools in the State Department of Education. The salary is from $1,800 to $2,100. Candidates must be citizens of the United States, legal residents of New York State, registered nurses and graduates of a registered nurse training school with at least five years' experience since graduation in supervision, administration or instruction in a nurse training school. Application forms and particulars of the competition may be obtained by addressing the commission at Albany.

Tri-State Medical Association.—The Tri-State Medical Association of Indiana, Michigan, and Ohio, at its annual meeting held at Put-in-Bay on August 1, elected the following officers: *President,* Dr. Charles D. Aaron of Detroit; *Vice-President,* Dr. F. T. Wood of Argola, Ind.; *Secretary,* Dr. W F. Schumaker of Butler, Ind.; *Treasurer,* Dr. J. A. Waltz of Montpelier, Ohio.

Southern Minnesota Medical Association. — This association held its annual meeting at Winona, Minn., on August 3, and elected the following officers for the ensuing year: *President,* Dr. H. L. Baker, Kasson; *First Vice-President.* Dr. G. J.

Tweedy, Winona; *Second Vice-President*, Dr. M. J. Hart, Leroy; *Secretary and Treasurer*, Dr. W. T. Adams, Elgin.

Medical Society of the Missouri Valley.—The nineteenth annual meeting of this society will be held at Council Bluffs, under the presidency of Dr. John E. Summers of Omaha, on September 6 and 7. Sessions will be held in the banquet hall of the Grand Hotel, and an excursion to Lake Manawa will be the social event of the first evening. The secretary of the society is Dr. Charles Wood Fassett of St. Joseph, Mo.

An International Congress of Life Insurance Examiners is to be held in Berlin, September 11 to 15, under the direction of Professor Kraus and Drs. Florschütz and Unverricht. The topics for special discussion will be pulmonary tuberculosis, syphilis, and obesity. The general secretary is Dr. Manes, Spichernstrasse No. 22, Berlin.

Obituary Notes.—Dr. W. J. Class of Chicago died at Benton Harbor, Mich., on August 10. Dr. Class was a member of the Chicago Board of Health and had done much work in connection with the recent epidemics of cerebrospinal meningitis and on the etiology of scarlet fever.

Dr. James Weir of Owensborough, Ky., died on August 8 at Virginia Beach, at the age of fifty years. Dr. Weir was graduated from the University of Louisville in 1878 and was the author of several medical and philosophical works.

Dr. Henry Rauch of Herod, Va., died on August 4, after an illness of several months. He formerly practised in Edgefield county, South Carolina.

Dr. Thomas D. Wooten of Austin, Tex., died at Eureka Springs, Ark., on August 1, at the age of seventy-seven years. Dr. Wooten was born in Barren county, Ky., and was graduated from the medical department of the University of Louisville in 1853. After practising in Tompkinsville and Springfield, Mo., he was in 1861 commissioned as surgeon of the Second Regiment, Seventh Division of the Missouri State troops, rapidly rising to the medical directorship of the Western Army Corps. In 1865 he settled in Lamar county, Tex., and removed to Austin in 1876. At one time he was president of the State Board of Regents, and had occupied many official positions. He is survived by his sons, Dr. Joe Wooten and Dr. Goodal Wooten.

Dr. S. A. Wilson of Battle Hill, Ga., died on August 5, after a three weeks' illness from pneumonia. He had practised medicine in Battle Hill for thirty-eight years.

Dr. George W. Mathews of Worcester, Mass., died on August 5, at the age of thirty-two years. He was graduated from the Medical Department of the University of Pennsylvania in 1895, and for three years practised in a suburb of Philadelphia. In 1898 he went to the Philippines as contract surgeon and soon after the organization of the Thirty-sixth Regiment volunteers he was commissioned captain and made assistant surgeon of the regiment. While serving in this capacity he was awarded a medal of honor for bravery by Congress for his gallantry in protecting the wounded under his care from an ambush. In 1901 Dr. Mathews was commissioned a first lieutenant in the regular army as an assistant surgeon and was assigned to duty in Fort Warren in Boston Harbor. Dr. Mathews' death was due to amebic dysentery contracted in the Philippines.

Dr. James B. McCaw died August 14, at Richmond, Va. He was eighty-four years old. Dr. McCaw was a surgeon in the Confederate Army and during the Civil War had charge of Chimborazo Hospital, in Richmond, where 76,000 Confederate soldiers were treated.

OUR LONDON LETTER

(From Our Special Correspondent.)

CANCER RESEARCH—CONTRACTED PELVIS—ADENOMA OF THE LABIUM—IRREGULAR PUERPERAL SEPSIS—THE TIME-BILL OF BEER—PHARMACEUTICAL CONFERENCE—CHEAP BEDDING.

London, July 27, 1906.

The annual meeting of the Imperial Cancer Research Fund was held on Wednesday. The report of the superintendent (Dr. Ernest Bashford) stated that the results of the first three years' investigations as to the spontaneous development of cancer in human beings have led to an alteration in the details of the work. In animals statistical study has been combined with experiment, and the attempt has met with some success. The facilities of the fund for ascertaining the occurrence of cancer in native races and within different geographical areas are unique. The data accumulated strengthen the belief that the two main types (carcinoma and sarcoma) increase in frequency with age. As to hereditary susceptibility, after repeated failures for three years, offspring has at last been obtained from mice suffering with cancer. An isolated case occurred in a mouse whose grandmother had it in the same way at the same site. It took four years and the examination of 100,000 mice to discover the occurrence of twenty-eight cases of spontaneous carcinoma of the mamma. The results of inoculations with eighteen of these tumors show that the frequency with which cancer can be inoculated is incomparably greater. As to rate of growth, 25,000 inoculations show fluctuations. When a growth was obtained, it often ceased and the tumor was absorbed; when growth continued, the evidence went to show that it was due to a revival of the proliferative powers in the cancer cells. Such alternations of amelioration and exacerbation seen also in human cancer suggest that they are essential features of cancerous proliferation occurring spontaneously, not the consequences of extraneous conditions.

Attempts to modify well established cancer gave little encouragement, though it had appeared possible to make mice very unsuitable for inoculation, but the report says nothing but harm can come from ignoring the fact that experiments do not enable them to arrest or retard the development, still less to cure the spontaneous developed disease. But the results compare favorably with the complete failure of all reputed empirical remedies forwarded to the laboratory to be tested. Four years' work has enabled the features of spontaneous cancer in mice to be reproduced and healthy mice to be protected from the consequences of inoculation with experimental cancer. "This having been achieved," the report adds, "it is not too much to hope that the further development of the experimental study of cancer will ultimately yield results having a direct bearing on the nature and treatment of the disease."

Sir William Church, who moved the adoption of the report, spoke hopefully of the future. Lord Strathcona, who presided, said they wanted £4,000 a year and for such an object it should be forthcoming. The King and the Prince of Wales, he said, were deeply interested in the work.

Dr. Nepean Longridge has communicated to the Obstetrical Society an account of sixty-four cases of contracted pelvis admitted during 1905 to Queen Charlotte's Hospital, where the system of admission, he said, made it possible to recognize and if necessary treat these cases early. The results were satisfactory, no death and no complication among the mothers; eight infants died, three of which had some abornmality incompatible with life. In fourteen cases labor was spontaneous and unaided, the most remarkable being a primipara who gave birth to a child weighing 5 pounds 12 3-4 ounces, through a true conjugate of 2 7-8 inches, in ten hours. The treatment of these cases was said to be narrowing down to a choice between induction of premature labor and cesarean section. Queen Charlotte's Hospital experience seemed to show that the former was satisfactory with a conjugate of 3 1-2 inches and over. The latter was the better procedure with a conjugate of about three inches or less.

Dr. Williamson showed a specimen of adenoma of the labium diagnosed as epithelioma and removed by Dr. Champreys in 1903, no recurrence having taken place. He suggested these growths arose in connection with sweat glands. Dr. H. Spencer doubted this, also their rarity. He

had met with two cases, and the tubules had a distinct arrangement which was inconsistent with the suggested explanation. The curator of the museum at University College regarded them as arising in sebaceous glands. Dr. Williamson replied that Dr. Spencer's cases were no doubt sebaceous adenomata and belonged to a different class to the specimen he exhibited.

The Edinburgh and Glasgow Obstetrical Societies held a joint meeting, followed by a dinner, on the 11th inst. A discussion on irregular manifestations of puerperal sepsis was opened by Professor Stephenson of Aberdeen, who said a knowledge of the site and character of the local lesion was of more diagnostic value than information about the organism. The graver forms of septicemia were not those discussed, but the milder, shorter, and rarely fatal deviations from the normal. The temperature of itself, he said, was not important, but the ratio between it and the pulse was. Intermittent temperature, though it rose to a great height, was of less importance than a slight but persistent rise. Prof. Murdock Cameron of Glasgow said the worst type was that in which nothing definite could be detected in the pelvis, but the patient took on an earthy color and had nausea and diarrhea. Such a case often proved fatal in the second week.

Dr. Barbour described two cases in which a puerperal rash developed, and suggested as an explanation the absorption of a toxin produced during the muscular activity of the uterus.

Dr. Easterbrook referred to puerperal insanity, which he divided into two classes. In one it appeared in the first week with high temperature and pulse, and other indications of sepsis. In the other it came on later and the temperature was subnormal. Such a case might be due to exhaustion of an unstable nervous system.

Dr. Kerr said rashes might be caused by enemata stirring up fecal matter, and further removal of mucus from the bowel might aid absorption.

Prof. Dickinson of New York described the case of a patient who had three severe hemorrhages—the first ten days after labor, the second ten days later, the third during the fourth week. The uterus was removed by vaginal route and a small septic focus found in the wall, which had opened a large vessel.

Dr. Oliphant mentioned a case in which he obtained a culture of the pneumococcus from the interior of the uterus. The temperature had gone up to 105° a few days after delivery.

Prof. Jardine had found sudden involution of the uterus tended to produce a high temperature.

The *Times* has followed its great puff of a "drink cure" by another of the same kind on Allsopp's beer! This last opens with an article by the *Times'* (advertising) staff on the food value of malt liquors, suggesting that the "health and vigor of the race are proof that these liquors are both wholesome and nutritious." It goes on to describe lager beer as a food, wholesome, mildly stimulant, "free from the objections to temperance drinks," as containing only 3 or 4 per cent. of alcohol, so that "only fanatics can criticise it on this ground." This audacious staff of the *Times* declares "there is the highest scientific and medical authority for asserting that a small amount of alcohol is a useful food." The next is called a "scientific appreciation" of the nutritive qualities of beer, and consists of just such a hash as an advertising staff might be expected to cook. This is followed by the "History of the House of Allsopp." But though the house has considerately sent me a reprint of the *Times* articles, I fail to find any reference to its financial position or the sorrows of the shareholders.

Of course the example of the *Times* was bound to encourage other papers in the down-grade. Already the *Standard* has followed with a leader-looking article headed "Startling Advance in the Cure of Disease—Medical Enthusiasm." The startling advance is rather in the degradation of the newspapers, and the enthusiasm perhaps in the proprietors at the influx of profit.

The Pharmaceutical Conference met at Birmingham on Tuesday and continues its deliberations until this evening. It was officially welcomed by the Lord Mayor, and on behalf of the medical profession by Sir James Sawyer, who spoke of the diagnosis of disease having been wellnigh perfected, but treatment was lagging behind, as to which the aid of pharmacy could not be dispensed with. The president was Mr. W. A. H. Naylor, and in his address he touched on the possibility of a faculty of pharmacy being established in the Birmingham University. He showed the relation of the newer chemistry and physiology to pharmacy, and indicated the directions in which research by scientific pharmacists is further required. He declared that the rubric of the conference, to which every member tacitly subscribes, is to maintain uncompromisingly the principle of purity in all medicaments, and held that many engaged in their craft devote their little leisure to the prosecution of pharmaceutical research.

The latest sanitary scare is the danger of cheap bedding, on which Dr. Taylor, public analyst to the Borough of Hackney, has reported to the Health Committee. He says that flock is made from old rags, too old and too filthy to be made into shoddy clothing. The process in a flock factory is devoid of any precautions. Old rags, largely made of old clothing in a filthy condition, smelling horribly, were received in bundles and without any preliminary treatment went into the machine, which tore them to pieces, rejecting buttons or metallic substances; then straight to a revolving "devil," whose long teeth further broke up the substance and by an air current exhausted through a flue into a settling chamber the dust. The friction caused heat enough to dry the flock, which left the machine free from odor. The flock examined, Dr. Taylor reports, yielded more bacteria than sewage from Crowness, and justified fear of spread of disease. It is certainly a repulsive story and supports the idea of some that clean straw is better bedding than many a flock mattress.

OUR VIENNA LETTER.

(From Our Special Correspondent.)

THE TREATMENT OF MENINGITIS—CONGENITAL DEXTROCARDIA—TUBERCULOSIS OF THE URETER—ALCOHOLIC CIRRHOSIS IN A CHILD—UNUSUAL POWERS OF MUSCULAR CONTROL—BALANTIDIUM COLITIS.

VIENNA, July 10, 1906.

A NEW method of treatment for epidemic cerebrospinal menigitis is being tried in Escherich's clinic with apparently very promising results. The therapeutic agent is prepared from bacterial cultures, and even in extreme dilutions it appears to be very effective against the meningococcus without possessing any undesirable properties. Escherich's assistant, Jehle, has gone to Silesia in order to test the new remedy, which is administered by subcutaneous injection, on a large number of patients.

Hochsinger has reported a case of congenital dextrocardia and cyanosis occurring in a child of six months. The child was a blue baby, and even when at rest the cyanosis of the lips, the tip of the nose, the toes and fingers was conspicuous. If the child became excited and cried out or wept the entire surface acquired a deep bluish hue, the condition being the typical morbus cæruleus. The pulse rate was 150 to 160 and the blood pressure 90 to 100; examination of the heart showed that this organ was completely transposed to the right half of the thorax. When at rest auscultation revealed pure sounds with accentuation of the diastolic valvular closure, but during excitement a systolic murmur was heard which was louder at the apex than at the base. The probability is that there was a defect of the septum. The radiograph was very interesting and revealed a semicircular shadow above the heart which probably represented a dilated pulmonary artery.

Zuckerkandl has operated on three cases of renal tuberculosis in which the kidney and ureter were both removed. In renal tuberculosis involvement of the ureter is almost always present and may even be more advanced than the lesion of the kidney. Tuberculous ureteritis is characterized by a dense thickening of the ureter which may attain the size of the finger, pain along the course of the ureter, and sometimes ureteral colic due to the narrowing of the lumen. The thickened ureter is sometimes palpable through the rectum or vagina and often also through the abdominal wall. The involvement of the ureter and kidney is frequently indicated by a unilateral cystitis encircling the opening of the diseased ureter. Zuckerkandl in these cases removes the ureter to the base of the bladder and carries a drain from this point to the lower angle of the incision, which extends from the costal border to the symphysis. A second tube is used to drain the renal pedicle. The abdominal wall is sutured in layers. By using this technique Zuckerkandl has always succeeded in obtaining primary union.

A case of alcoholic cirrhosis in a boy of six years was observed by Neurath. The patient suffered from extreme dyspnea, the abdomen was enormously enlarged and protuberant, there was great edema of the abdominal wall, the lower extremities and the scrotum, the abdominal veins were dilated, and there was a great deal of free fluid in the abdominal cavity. The liver appeared greatly enlarged, particularly the right lobe, the lower border of which could be felt half way between the umbilicus and the ensiform. The spleen was enlarged and hard, the heart was normal, and the rather scanty urine contained no albumin. It was learned that during the past four years the parents had given the child from a half to two liters daily of cider, and on examination it was found that this contained 3.93 per cent. by volume of alcohol. So far diaphoretics and diuretics, as well as stopping the alcohol, have not brought about

any improvement in the patient's condition and Talma's operation has been suggested.

A man has recently been exhibiting himself in the various clinics who possesses unusual powers of muscular control. He is now thirty years old and at the age of sixteen years he had typhoid fever, after which he suffered severely from constipation. In order to secure a movement he was obliged to exert his abdominal muscles to an extreme degree and in this way he gradually got to the point of being able to bring separate portions of these into action so that wave-like contractions would appear. Two years ago this ability was noticed by a physician, who pointed out its interesting nature to him, and since then the patient has acquired a number of new tricks of this sort, for in wandering from clinic to clinic in Germany and Austria he has everywhere been encouraged by the physicians who have seen him to learn to control new muscles. He is able to innervate the external oblique muscle as a whole or only in part and he can also invoke contractions of the separate portions of the rectus between the tendinous inscriptions. Another interesting and astonishing feat is his ability to force the small intestine up into the thorax, and he is also able to dislocate the apex beat to the left side beyond the mammary line and to the right as far as the sternum. These movements are produced by unilateral contractures of the abdominal muscles. He is able to produce unilateral contractions of the platysma and he can raise and lower the larynx by moving the hyoid bone up and down. An entirely different sort of control is manifested in his faculty of producing voluntary contraction or dilatation of the pupils on either side. The dilated pupil reacts to light as well as on accommodation. The man states that when he is learning a new innervation he can practice this only a few moments daily, as fatigue sets in rapidly. His feats are interesting, from both the physiological and neuropathological standpoints, as they throw an interesting light on hysterical contractures and paralyses. His control of the movements of the pupil shows that these also possess a cortical center and that the hysterical pupillary palsies have a physiological basis.

A case of balantidium colitis has been studied in Neusser's clinic. The patient was a woman of thirty-six years, who went to the hospital on account of severe diarrhea. On examination she was found to exhibit characteristic symptoms of tabes, and an enormous number of the *Balantidium coli* was found in the very numerous fluid stools. This organism has heretofore been discovered in the stools in ninety cases of enteritis. The parasite is a harmless inhabitant of the intestine of the pig which probably is to be regarded as its host. It is, therefore, interesting to note that the patient stated that her diarrhea began shortly after the ingestion of some spoiled ham, in which possibly the cystic form of the parasite might have been contained. The course of the disease is usually fatal and so far it has been observed mainly in the northern countries of Europe, such as Sweden, Finland, and Russia, though cases have also been reported from Germany, Italy, America, Asia, and Africa. This case is the first observed in Austria.

OUR LETTER FROM COPENHAGEN.

(From Our Special Correspondent.)

THE CAMPAIGN AGAINST TUBERCULOSIS IN DENMARK—HEALTH LAWS—MODE OF ACTION OF THE FINSEN LIGHT—AMERICAN VISITORS TO DANISH HOSPITALS.

COPENHAGEN, July 9, 1906.

THE Danish National Association for Combating Tuberculosis has just issued the report of its work during the last year. It is very interesting to notice what an association like this one, entirely private in its character, has been able to accomplish during the few years of its existence. It was started five years ago by a comparatively little circle of prominent men in different walks of life, among them, of course, many medical men. It carries out its work chiefly by means of voluntary contributions from its members, now numbering 28,000; during the last year it collected a sum of more than $40,000. At the time of the formation of the association Denmark had only one sanatorium for pulmonary tuberculosis; this establishment had been built and financed chiefly by the Danish medical profession. The association then took up the task of providing sanatoria for the poorer classes of the population, with the result that it has built up to the present three sanatoria, with a total of 250 beds, while one more is actually under construction and the building of two more is planned. As stated these sanatoria are meant for the poorer classes; the patient pays only 20 cents a day, the rest of the expenses, caused by his treatment in the sanatorium, being defrayed by the state and the association. In order to show how thoroughly the importance of combating the tuberculosis is realized by our population I may mention that our farmers have already built one large sanatorium for the treatment of their fellow-farmers and their families, and that the erection of one more is resolved upon. When I add that the municipality of Copenhagen has a tuberculosis sanatorium of its own of 145 beds, a tuberculosis hospital of 300 beds, besides wards receiving cases of pulmonary phthisis in others of its hospitals, it will be seen that we are doing our best to combat the great white plague.
